THE MEDICO-LEGAL ASPECTS OF FRACTURES OF THE BONES OF THE EXTREMITIES, AND OTHERS, FROM A CONSIDERATION OF THEIR ÆTIOLOGY, DIAGNOSIS, PROGNOSIS, AND TREATMENT.*

By THOMAS H. MANLEY, A. M., M. D.,
VISITING SURGEON TO HARLEM HOSPITAL.

THE disorganization of bone from traumatic influence or fracture belongs to that category of what may be designated serious surgical lesions. Of all others of the latter class, these are by all odds the most common.

Every practitioner of the healing art sees them, and nearly all are assumed to be competent to properly treat the simple types. No age, sex, or condition escapes them. In varying degrees, according to the age of the patient, general health, and character of the lesion, they always leave a defective limb.

In early life Nature effects her work of repair so perfectly in many, when appropriate treatment is instituted, that the patient, after adult years are attained, is scarcely conscious of any impediment in function or diminution in strength in the former injured limb; hence it is only when it is put on a severe, protracted strain, in the event of sudden changes in the weather, or as one advances into old age, that he is reminded, by a sense of weakness, twinges of pain, and a tender point over the seat of injury, that the limb's integrity was ever damaged.

Many types of fractures in early life by the simplest description of treatment undergo prompt repair without any visible evidence of them remaining. Others, regardless of what measures may be instituted or skill and experience brought to bear in their management, never unite by an osseous isthmus, shortening or deformity of the limb always remaining. Although time and custom have sanctioned the division of fractures into two groups—the simple and compound—this is but an arbitrary arrangement, and tends to rather confuse than to elucidate, for all fractures are essentially compound or complicated. Not a few so-called simple fractures are more difficult to manage and cure without greater deformities than those designated compound.

It is not infrequently quite impossible to definitely diagnose fracture. Many of them extend into the articulations or are complicated with more or less luxation. As the union of fractured bone is effected by two distinct processes—by primary intention without a callus, or by extensive homologous cell proliferation with a provisional mass encircling the ends of the bones, in a considerable number as early as the second week—it may be quite impossible to say from any physical examination without the employment of considerable force whether or not the bone had been dissundered at all.

In a general way it can not be said that the antiseptic treatment of wounds has in any manner revolutionized or improved on the principles recognized for ages as most appropriate in the management of simple fractures; though since Listerism and cleanliness have been introduced, osteotomy has been more freely practiced for distortions of bone and non-union with better effects than before they became current with the profession.

Medico-legal Questions in their Relation to the Ætiology, Diagnosis, and Treatment of Fracture.—It might seem, on first thought, that a question of litigation or jurisprudence could scarcely enter into the consideration of the causation of a fracture; but there are many cases on record in which actions in civil and criminal suits have rested mainly on this feature alone.

The situation and extent of injury have not been disputed by the defense, but they denied their responsibility by alleging that "the plaintiff was injured in another manner than that represented by him or her."

Cases of this description are not uncommon.

The inducement, by a little deceptive circumsppection, with the unscrupulous, to turn an accident to good account often is very great. As individuals and corporations are almost wholly at the mercy of the surgeon in these cases, it behooves him under all circumstances, when he has the least suspicion, to examine the patient critically for surface lesions and demand from him a full and complete account of how the injury occurred. In many the physical examination alone will not decide the quality and extent of force sustained, whether it was direct or indirect, or whether the body came in contact with an object or he was struck by an object. When we remember that fracture in rare instances may ensue from muscular violence alone, we can then better appreciate the difficulties which beset us in many of these cases in which fraud is suspected. If the surgical attendant will debase his profession to deliberately support a criminal extortion, or is very discourteous to the defense, of course the way is blocked and the issue of the case must largely be left with the jury in deciding on the veracity of the plaintiff.

It is of prime importance in every case of fracture to investigate into the patient's general condition; or at least we can casually make note of it.

Is he deaf or near-sighted?

Is he rheumatic, gouty, syphilitic, or in greatly reduced general health?

Has he ever been injured before, and, if so, in the same limb and how many times?

Even an approximate determination as to the precise manner in which a fracture has been produced is occasionally extremely difficult to reach. It is certainly marvelous and often quite inexplicable how one may fall fifty feet or more and entirely escape, while another may fall one third the distance, or less, and sustain multiple and grave fractures.

But there are fractures which have quite absolute and unique histories of their own, which, when we are familiar with them, will not deceive us.

* Read before the Section in Medical Jurisprudence of the Pan-American Congress, September 7, 1893.

Fractures near the epiphysial end at the radiocarpal or the tibiotarsal articulation are usually the outcome of indirect violence. Fractures far removed above the joints are generally the outcome of force directly applied. This is notoriously the case in those of any part of the ulna or fibula shafts when complicated.

The diaphyseal center of the humerus, too, is seldom broken except by the application of direct force.

This generally holds good with the same anatomical structure of the femur.

Apophyseal fractures are, with rare exceptions, the result of indirect force.

The only exception to this general rule would be the elbow joint of the youth. The clavicle usually fractures in consequence of indirect violence.

The body of the scapula, the pelvic bones, the carpus, tarsus, metacarpal, metatarsal, and phalangeal bones fracture rarely, except through crushing force applied over them.

The late Professor Darling, of New York, used to say that one should recognize the ætiological factors in broken ribs by the direction which the fragments took after injury. He taught that when the vulnerable force was applied directly over the costal convexity the ends broken off must needs penetrate the pleura, and perchance damage the pulmonary organs underneath; but when the force was applied indirectly, as by antero-posterior pressure or by muscular action, then the respiratory organs would escape. As fractures of the skull constitute a unique and independent class of injuries which, in their physical qualities and clinical phenomena, present characteristics peculiar to themselves, they will not be embraced in this review.

Fractures of the spine possess no definite physical or clinical characteristics. A current impression prevails that a broken back—a fracture of the spine—is always a very grave injury, which necessarily must entail a permanent crippling; but this is erroneous, as has been repeatedly demonstrated, for it is only when the cord is simultaneously damaged that paralysis succeeds in consequence of the fracture.

Fractures of the spine follow direct and indirect force; the latter more frequently.

When they occur as a consequence of direct, concussive force, the consequences are more serious.

Fracture of the lingual or hyoid bone is an exceedingly rare lesion. I have never met with one in more than three thousand fracture cases. In modern times, since the rapid and enormous extension of the iron railroad, very many are crushed or maimed by vehicles which are rolled over them.

The fracture is more commonly compound when the wheels roll over the limb; but there are many exceptional cases in which the integuments are unbroken, yet the bone has sustained extensive shattering, the neural or vascular trunks being seriously damaged.

The extent of damage to the limb after having been run over by car wheels will depend on many factors directly connected with the patient, but more often on the weight of the car, whether a street car or a steam railroad

car, freight or passenger; whether or not it was loaded or empty; whether one or both wheels passed over the injured limb; and whether the car was in rapid or slow motion. So many cases have come under my observation in which one or both wheels have passed over a limb on a street railway without destroying its integrity, or even causing a fracture, that I am convinced that we certainly can no longer entertain the view that an accident of this description will always irretrievably destroy the limb. In all cases in which shamming is suspected we should carefully examine the clothing and look for abrasions, ecchymosis, or discoloration of the integument.

These accidents seldom occur except to young children, those physically incapacitated, or to the intoxicated.

Steam-railroad injuries of the limbs constitute, practically, a separate class of fractures. With these are two sets of symptoms, seldom associated with tramway accidents.

There is commonly bodily organic injury as well as the local disorganization. The former may quite overshadow the latter in importance and gravity. It is well, in all these cases, to determine the extent and degree of bodily injury present, if possible, at the first examination.

Another element of far-reaching importance is that of a psychological character; the element of fright, of nervous shock.

It has long been noticed that when those who are injured on railroads are employed on them, the extent of shock is not so great as when the same degree of traumatism is borne by a passenger or others. A limb run completely over by the car wheel on a steam railroad of a trunk line must inevitably sustain great damage, and in the vast majority of cases is completely destroyed.

I have no recollection of having ever seen a limb survive which has been rolled over by the wheel of one of these freight or passenger cars, though there are records of such injuries where the limb has escaped. (Dr. J. B. Murphy, of St. Paul, has reported such a case to me.)

It is almost needless to say that, in all this class of injuries, the fractures are compound. But it is well to note that the living integument is a very tough tissue, and hence in many, while there may be but a small opening in the integument, the inclosed bone and muscle are ground to a pulp, the main arterial trunks and nerves being completely torn through.

Fracture Dislocations.—The ætiology of fracture dislocations is generally definite and simple. With the exception of machinery accidents, they are seldom, if ever, induced except by indirect force; but at the elbow they more commonly are occasioned through violence, acting immediately over the seat of injury. The causative factors in a Colles's or a Pott's fracture are so well understood and so constant that we would regard with suspicion a fracture belonging to either of these in which it was alleged that it had been induced by a blow or by being run over.

We shall very rarely, if ever, induce a dislocation by any measures which we may employ in treating a fracture; but, unhappily, the converse is not the case. The humerus

is often fractured below the surgical neck in the effort to reduce a dislocation of the shoulder.

Two such accidents have occurred in my practice—one in a man and one in a woman. Many years ago I saw this accident happen in Bellevue Hospital while Frank Hamilton was assisting in the reduction of the joint.

In both of my cases the bones remained out of their sockets. No case has come to my knowledge in which a civil action has been brought for damages after this complication has followed. And it is difficult to conceive how ground for action could be reached when ordinary precautions are observed.

Fractures resulting from the Attempted Liberation of Ankylosed Joints.—All ankyloses of joints are attended with an atrophy of the muscles which act on them and the bone substance of the shafts on the proximal end of the immobilized joint. It is quite impossible, in many cases, to determine the nature, extent, or situation of the pathological conditions which cause the ankylosis. It may be osseous or ligamentous, or it may be caused by extensive adhesions between the muscle sheaths, degeneration, contracture, or shortening of all the flexor muscles. If the case is not most carefully studied, its pathology fully appreciated, and force skillfully and judiciously applied, damage may follow force. The femur has fractured once in my hands, while I was trying to break up an ankylosis of the knee joint.

In attempting the same procedure on two others, I have fractured both patellæ, much to the increased strength and power of motion of the limbs in both the latter cases.

In many types of knee-joint ankylosis this is a procedure which is rather valuable as a therapeutic measure than a source of ultimate detriment to the limb. In fracture of a shaft, unless every possible precaution was employed, particularly in liberating an ankylosed joint, were complications to follow the accident, the question of damages might be raised.

Forensic Consideration of the Etiology of Fracture.—On a superficial view of the subject, one might assume that the surgeon had performed his part and fully discharged his duties in a case of fracture when fair structural and functional restoration had been secured without deformity. As far as one's legal obligations are concerned, this view is correct. But in this country and in our times—when the sanctity of an oath is indifferently regarded, when perjury is rarely punished, and when so many maintain themselves by resort to sharp practices—it behooves the attendant, in the interest of justice and science, to examine with great caution every case of fracture or dislocation very critically in which he has the slightest suspicion of the perpetration of fraud. A designing person may, through a ruse, go through the farce of being injured. He may have had an old dislocation, an ununited fracture, or a deformity which may present many of the characters of an impacted fracture. Now, with a few well-coached pliant witnesses and the testimony of a reputable practitioner, the plaintiff is in a fair way for recovering heavy damages if neglect of an individual or corporation can be proved.

It is, then, of cardinal importance that the causation be

clearly established in every case of fracture which comes under our observation. But how can we determine the recency or proximate causes of a fracture in most cases?

Means for elucidating the Causation.—By a rigorous examination of our patient as to his general condition and the local condition of the parts. In every case of a fracture or dislocation, if seen within twenty-four hours, well-marked constitutional disturbances are generally present. As a general rule, with very few exceptions, in all cases of fracture of the long bone shafts or dislocation of the major articulations the body sustains simultaneously more or less shock; but should evidence of this be absent, or present in only a mild degree, phenomena of reactionary inflammation are present. There is immediately after injury a pallor of the features, the general integument is pale and anæmic, the pulse is weakened and quickened, and, if we observe the patient cautiously, we shall notice well-marked diminution in bodily strength.

On the day following the injury, constitutional symptoms are more marked and accentuated. Now we should find evidence of surgical fever, elevation of temperature with a full pulse, with an expression of the countenance which bespeaks bodily suffering. This latter in simple fracture is not always well defined.

Local Condition of the Parts.—The "age" of a fracture, whether recent or of long existence, can be definitely determined by a rigid local examination. The same will apply to dislocations. We will first note the state of integument, as to whether it is bruised or lacerated, whether we have evidence of sanguineous extravasation or tumefaction.

Abnormal mobility of the fragments with crepitation is unmistakable evidence of fracture.

Mobility in itself avails us but little information with respect to acuteness or chronicity of a fracture, for we may see it in an old fracture, and in the recent impacted type it may be wholly wanting; but *fracture crepitus* is an unerring monitor.

No tongue or pen can adequately describe the tangible qualities of this sensation. That harsh grating sensation which it transmits to the hand has no parallel in any other physical phenomenon whatever. It must be felt repeatedly to be fully appreciated; but when we are acquainted with it, it can never deceive us. In an old fracture or dislocation atrophic and arthropathic changes, when carefully sought for, will stamp the true character of the lesion. Difficulty is only encountered in very fat individuals, mostly females, in whom the joints and bone shafts are often covered in by dense layers of adipose tissue.

On the Manner in which a Fracture has been Sustained.—Has the bone been fractured by muscular action or extrinsic force, by direct or indirect violence?

A fracture of bone from muscular action alone can occur rarely, except when the elements of the bone are the seat of pathological changes—as cancer, or osteomalacia, etc. The only exception to this, perhaps, is in the case of the patella.

But, from my own observations, I am inclined to believe that this is a lesion rarely attributable to muscular action alone. In about thirty cases which have been treated

by me, in none was fracture wholly attributable to this cause, but rather to indirect violence.

A fracture of a shaft from muscular action I have never met with. In a general way we know that in the great majority of the most common types of fracture they have a definite etiology.

We know that Colles's fracture at the wrist and Pott's ankle fracture are always attributable to indirect force, as are also many fractures of the lower end of the tibia, while fractures of the femur, the fibula, and the ulna most commonly occur in consequence of direct violence. This is generally true, too, of those fractures which involve the upper third of the tibia or fibula, when separately fractured; the radius and ulna; and the humerus in any of its segments.

The shafts of bone are sometimes fractured *in utero*, we are informed; but this must be a very rare accident.

I have never seen such a case, or seen a report of one in the current literature of surgery within my recollection. Indeed, with the osseous structures yet in a cartilaginous condition until the fetus is fully developed, it is difficult to conceive of the possibility of such a lesion, except in the latter stages of pregnancy, when, should such a traumatism be borne by the uterus through violence applied over it as to cause fracture of a fetal bone, it seems inevitable that life itself must be seriously imperiled. It is very probable that such few cases as have been reported were those in which the bones were broken in their passage through the canal of emergence.

Fractures of the femur during delivery are not uncommon, but they almost invariably unite promptly and leave no trace of deformity.

Fracture of Bone in Mortal Injuries.—The question as to the precise date of fractures which have been found post mortem has occupied an important position in many medico-legal cases; but, as they pertain in the greater number of cases to skull injuries, an extensive consideration of them here is not necessary. Ogston (*Forensic Medicine*, p. 514) alleges that "the presence or absence of a blood-clot in a fracture detected post mortem is not of any definite value in determining whether a bone was fractured before or after death," and says that "the only real test is the presence of reparation processes," and that this only can the medical jurist rely on. He adds, though, that a clot found between the ends of the fractured shaft is decisive proof that it was of an ante-mortem character. In this, however, Casper does not concur. Devergie (*Médecine légale*, vol. ii, p. 101) tells us that every shaft of bone fractured completely after adult years are attained results in a diminution of the volume of the bone, which, in the living or the dead, is easily appreciable in thin subjects, but that in fat subjects, particularly women, this is not easily detected. In the absence of a well-defined callus, this, he says, is important to remember.

In considering this part on the etiology of fracture from a forensic standpoint it is well to always determine, if possible, by a thorough scrutiny into the patient's or subject's history, whether he had a predisposition to fracture, had a preternatural fragility of the bones.

On inquiry in fracture cases in my hospital service, very many instances have come to my knowledge in which the patient has previously fractured other bones of the skeleton. Many have come under my care in which the most trifling sort of force had broken the bone. Ogston (vol. ii, p. 210) cites the case of a carter who, in jumping from the shaft of his cart, fractured both of the femora in their centers. He mentions another case, which ended mortally, in which but a slight blow on the shoulder so shattered and shattered the head of the humerus and upper third of its shaft that the man succumbed to it. On autopsy, it was found that the bone was composed wholly of a friable compact tissue.

In all these cases, on examination, we should sedulously inquire into the patient's general condition, with a view of learning if he were in any way invalidated by a pre-existing local or constitutional infirmity—as ankylosis, the wearing of artificial limbs, rheumatism, or paralysis, or any other infirmity which would in any manner interfere with locomotion—as they must, each and all, be regarded as indirect but important factors in the etiology of many fractures and other injuries.

Diagnosis.—It is of fundamental importance that a correct diagnosis be reached, if possible, on the first visit. Many a medical attendant has come to grief through neglect to rigorously observe this rule.

It is true that there are often many obstacles in the way at one's first visit. First, the fracture, if recent and close to an articulation, may be of such a character as to defy detection; and if many hours have elapsed before it is seen, inflammatory changes with intumescence of the adjacent parts may be so great as to quite completely mask the indubitable symptoms. The bone may have been fractured transversely without any displacement, and the temporary muscular spasm, always present when reactionary inflammation has set in, holds the fragment in firm apposition. It may be said that, with many fractures, their recognition is indispensable rather from a medico-legal standpoint than with respect to treatment. Many fractures, from their situation, are extremely difficult to recognize without the aid of an anæsthetic and one or more assistants. This is particularly true of the proximal end of the femur and fractures which involve the elbow joint.

A fracture of the anatomical neck of the humerus may be mistaken for a dislocation if great care is not exercised. There are types of luxation and subluxation of the radio-carpal articulation which, on superficial examination, present some of the characters of fracture, and *vice versa*. Secondly, we may encounter impediments from the patient and environment. The patient, if a woman, may, through a sense of modesty, be reluctant to permit the medical attendant to expose her in his examination. She may allege that she has but a *sprain*, and that such examination is not necessary. Her word may be confidently taken, and an examination not insisted on.

Such a case occurred in New York very recently.

The patient, an actress, had been kicked by her husband in an altercation, the blows falling on the leg and knee joint. Very great pain following, a neighboring physician was called

in, who examined her limb under her garments. He prescribed a liniment and made light of the case.

Later another physician was called, who detected a fracture of the patella, with some inches of separation of the fragments. I was invited in to verify the diagnosis. A civil action was instituted against the first medical attendant, and a verdict was found for the plaintiff.

One may be called late in the night far away from associate medical aid, or to one wholly unable to pay the expenses of a consultation. Our patient may be hypersensitive, intoxicated, boisterous, or unmanageable. But the law holds us equally responsible for all. In large cities and populous towns there is some relief for us in these cases by sending them to the hospital; but in small villages and scattered country sections we generally can not shift the responsibility. Most of our mistakes in diagnosis arise from haste or an imperfect knowledge of the anatomical and physical qualities of fracture.

A few years ago a vigorous young laborer came to me to attend him for a fractured clavicle. He had a few hours before been at one of our most noted dispensaries, and the shoulder was already firmly adjusted by a modified Sayre's dressing and enveloped in several deep layers of a copious dressing. But he had great pain and demanded a redressing. I sent him back to the dispensary from whence he came, reminding him that most public dispensaries are schools for instruction, and that what he got for nothing must be generally valued accordingly.

In a little while he returned again, begging me to examine the distracted joint. He had been at the dispensary; but besides a nicking of the edges of the dressing with a scissors, nothing had been done. On removal of all the dressings I discovered no injury of any description.

We can well imagine the consequences to a healthy limb and articulation in such a harness for six or eight weeks.

An elderly woman went marketing one winter's night, slipped on the curbstone of a sidewalk, and was unable to rise. An ambulance was called and she was entered into the surgical ward of one of our principal hospitals. The house staff, wearied after a heavy afternoon clinic, made a hurried examination, pronounced her case one of fracture of the head of the femur, and put the limb up in a Buck's extension apparatus. She was informed that she must keep the bed for six or eight weeks, and that she would be lame for the remainder of her life.

Her friends sought her out and, in spite of the protests of the doctors, brought her home the same night. At about midnight I was called, and, on examination, discovered that there was no fracture of any kind, but a dislocation backward of the head of the femur on the *dorsum ilii*. With the employment of a strong clothesline and three strong young men boarders whom she had, I was able to readily reduce the displaced bone. In two weeks she was about as usual with scarcely a perceptible limp.

In doubtful cases of fracture we should always insist on a consultation, or advise the patient of our doubts. Then, should deformity occur, we are not responsible for it or the error through which it exists.

Surgeons and practitioners are sometimes called in after a case has been under the care of another practitioner, and in which, possibly, it may be alleged that there was no fracture, but that the practitioner had tried to "make a

case" of it, with a view of extorting a fee or aiding the patient to secure damages for a spurious injury.

In this connection it is important to inquire if there were any physical evidences during life by which we could determine whether or not there has been a fracture sustained, when we can only examine the limb at some distant date after the alleged injury.

In the case of the fracture of the femur or humerus in an adult it is my conviction that imposition is quite impossible. In any simple fracture in a growing child, or one which involves the tibia, fibula, radius, or ulna of an adult after the first week, there are no means known to art by which we can determine this question with definite certainty. It has long been known that bones, like the soft parts, unite by two processes—one known as *primary union*, and the other by *secondary union*. In the latter we always find a callus; in the former not necessarily. This I have repeatedly demonstrated in my own fracture cases in and out of hospital.

Within the past year a case came under my observation in which a gentleman had injured his right leg, and this question arose. He had been injured nine days before I saw him. At this the attending physician called in one of our best-known surgeons, and it was agreed that he had fractured his right tibia in the lower third. At my request, the plaster dressings were removed, in order that I might examine the bare, unencumbered limb. The patient persistently protested that he had no fracture. I could certainly discover no evidences of any.

But I, nevertheless, knowing the respectable character of the previous attendant, besides bearing in mind those occasional cases of primary union and practically *non-callosed* fractures, advised the family that there had been a fracture, and recommended the removal of the heavy gypsum case, now rendered unnecessary. Indeed, in simple fracture cases in the young and vigorous, in the event of a litigation over a case, the defendant is quite at the mercy of the medical attendant. Therefore the practitioner who would uphold the honor of his profession and refuse to be an accomplice to a crime must exercise great caution that he does not prematurely designate a sprain a fracture, and thus work a very serious injury against an innocent party, and strike at the very foundations of civilized society by compounding a felony. It is a humiliating admission to make, but justice demands that one's experience should be made known, and hence I must confess that, of late years, many cases of alleged fractures and other injuries have come to my knowledge in which no bodily traumatism of any kind had been borne, but the cases had been "worked up" for the purpose of extorting money. These accident insurance companies and tontine societies are a great inducement to dishonesty and extortionate practices.

A case came to my knowledge within the past winter (1893) in which a physician was approached by a gentleman who had been his former patient, and informed him that he was carrying an accident policy which would pay him fifty dollars a week, in the event of accident, for ten weeks, adding that he was then in straitened circumstances, and had the audacity to ask the doctor if, for a consideration of fifty dollars, he would splint his arm and treat him for a pretended fracture of it, so

that he might raise some money from the company on a medical certificate.

Diagnosis of Complications attending Fracture.—It is well to remember that in most fractures resulting from violence, simultaneously with the bone disorganization, there is severe bodily shock with possibly other structural or organic lesions resulting from the same influences.

This is particularly true of railroad and machinery injuries. There may be a dislocation with the fracture, or there may be fracture of other bones, notably of the skull or ribs.

In recent times spinal shock or concussion of the spine is not unfrequently said to attend as a complication of fracture. In all those serious cases, in the interest of all parties, it is an imperative duty that a minute scrutiny of the entire body is made at the primary examination, or as soon as the patient is in a condition to safely bear it.

Prognosis.—A clear conception of the causes of a fracture, with a comprehensive knowledge of its type or character, opens the way to a reasonably safe prediction as to immediate and remote results.

Very often, when called to attend one suffering from a broken bone, we are persistently importuned by the relatives or friends of the patient for an opinion or an assurance as to the ultimate utility of the limb after treatment is ended. Here we must exercise great tact not to compromise ourselves by too optimistic promises, nor, on the contrary, by too somber insinuations, unduly discourage or alarm.

To commit the former would be to leave us open to severe censure or a prosecution in the event of disappointment; and the latter might cause us the loss of the case, very much to the detriment of one doing a village or country practice. The succeeding practitioner, though perhaps fully realizing the serious character of the injury, would inspire his patient and those about him with hope, and yet hedge in such a way as to escape criticism, when, though the limb were defective, the patient and his friend would be ready to swear it was perfect.

Every one, from the meaneast to the highest, in this world, under ordinary circumstances, by an instinctive impulse, will invariably endeavor to minimize or conceal his infirmities, and the fractured invalid is no exception.

An intimate familiarity with the clinical history and sequelæ of each individual case will usually warrant us in venturing an opinion after the fracture has been definitely recognized. We will be guarded in the main by the age of the patient, the condition of general health, the nature and situation of the lesion, the absence or presence of complications, the facilities for treatment, etc.

But in no case can an absolute opinion be vouchsafed, inasmuch as we know nothing about our patient's peculiarities; for a bone may fail to unite, the soft parts will not bear protracted pressure, and ankylosis, shortening, deflection, wasting, gangrene, or persistent weakening in the limb may follow. These are unusual but possible sequelæ even in the hands of the most experienced.

No one will be rash enough to promise anything approaching perfect functional or structural restoration in a

fracture which involves an articulation—one opening into the elbow joint, an intracapsular fracture at the hip joint, a Pott's, a Colles's, of the ankle or wrist joints—nor will he forget to remind his patient of a probable shortening in any type of complete femoral fracture at any age.

But we may say, in all cases of fracture of every description, that a defective limb will always follow any line of treatment. This we may always maintain from the fact that normal histological bone, once destroyed by either disease or trauma, is never reproduced; that the substitute which Nature provides for repair, while fulfilling in a large measure the function of the damaged bone shaft, is yet but a species of ossified cicatricial tissue, without the vitality, strength, or resiliency of what it has replaced. We may add, too, that the younger the patient the better the prospects of functional restoration; while, on the contrary, at or past the meridian of life, anything like perfect restitution is out of the question, and permanent weakness must remain in varying degrees.

Treatment.—The surgical therapy of fracture has been the rock which has wrecked many an unfortunate practitioner.

In past years, in the United States, a considerable number entered at once into active general practice with little or no practical experience in dealing with injuries. Clinical knowledge was not an essential requirement for a medical degree, and hence, when the surgical tyro was called to his first case of a seriously complicated fracture, very naturally his patient's escape from death, the loss of his limb, or a deformity, might be attributed to good luck as much as to the skill and experience of the medical attendant.

The law does not expect impossibilities, but it does demand of those who practice the healing art as general practitioners that they possess a reasonable knowledge of the principles which underlie it and their application; that one is acquainted with the plan of treatment called for in those cases which he assumes to manage. Of the specialist in any line of practice, whose fees are larger, much more is demanded, and his responsibility is proportionately greater.

Very naturally, when one has confided the management of his shattered, distorted limb to our care, it is presupposed that he authorizes us, as far as is within our power, to provide every possible resource of art and science to restore the usefulness of the limb.

Therefore, as many complicated and serious fractures possess unique and peculiar features, as a preliminary step of cardinal importance, in all of these cases a consultation should be insisted on.

When this is not practicable to be had with an experienced surgeon, then the most skilled general practitioner should be invited in for assistance. But should the family or friends demur to a consultation, decline to bear its expense, or for other reasons a consultation can not be had, then the attendant should have it clearly understood that the responsibility of failure in treatment must rest with his patient and friends, when he is, in a measure, relieved of any further embarrassment.

But in some places at the present time in the United States there are many and important reasons why a consultation should be discouraged in almost any event. In certain localities and States a consultant is permitted to continue his visits as often as the medical attendant requires it, or it is desired by the patient or deemed necessary by himself. This vicious clause opened the way to professional piracy and left the family physician at the mercy of the consultant. And hence of late years, in the city of New York and other places, many have not failed to take advantage of the amended code, or no code, to firmly intrench themselves and tenaciously continue their visits until the first physician is ousted.

The last thirty years has witnessed a revolution in the treatment of fractured limbs, and accordingly what were laid down as orthodox measures in the recent past will not hold now, though it must be admitted that the fundamental principles of fracture therapy yet remain. Change has been rather in the direction of detail than the adoption of new principles. Tenotomy, the extended posture with traction weights, the gypsum dressings, resection of bone as a substitute for primary amputation, all belong to modern times, none of which would have been possible without the inventions and discoveries of which these were the legitimate outcome. Accordingly, it might be fairly asked if the physician had done full justice to his patients who had not utilized all the materials and facilities which modern science has rendered accessible.

Right here is where the difficulties arise; for it might be inquired, Have all those innovations in fracture treatment been an advance over measures formerly in vogue?

It is perfectly rational to inquire if it is a prudent plan to fix a fractured limb in any sort of immovable dressing immediately after injury.

Is the extended position with weights, or not, a gain over postural treatment—muscular relaxation with flexion?

Is plaster of Paris in a general way more conducive to simplicity of treatment than the older custom of segmented splinting?

Is tenotomy a measure which may be generally adopted in cases of extreme rigidity with overriding of the fragments?

Considerable difference of opinion prevails among the most eminent authorities at the present day on these questions, which is an evidence that none of them carry the force of dogma. It is one's experience to now and then be called to a case in which for many reasons it is inexpedient to invite in a consultant. The patient injured is in no great pain, but it is quite impossible to say whether there is a fracture or not. Under these circumstances, what should be our course of action? Or, should we encounter a case in which, on consultation, no unanimity of opinion can be reached, what should be our line of conduct?

In the former, our interests will be better guarded by always applying some sort of temporary adjustment and watching the case until time will decide. In the latter, the opinion of the majority should prevail, if there be a third party; at the same time the injured and relatives should be candidly informed of the difference of opinion.

Many practitioners have come to trouble by overconfidence in their own capacity and knowledge or by an unskillful, imperfect, or hasty examination. The classical symptoms of fracture are wanting; the hypersensitive patient resists forcible manipulations, without which the definite recognition of certain fractures at certain times is utterly impossible.

The patient will vehemently proclaim that he has no fracture because "he can move his fingers or toes." A simple lotion is perhaps prescribed and the case dismissed. Possibly nothing more is heard from it until the first medical attendant is served a notice for a suit, when abundant expert and other testimony is forthcoming to incriminate him for the neglect through which the patient suffered in consequence of unnecessary pain by protracted treatment, or perhaps now he has a deformed limb.

Malpractice essentially consists of two phases: (1) *The passive, in which one's course is not sustained by general authority.* (2) *When those measures in treatment are omitted which might have approximated to perfection in results.*

Very naturally, those fractures which lie close to or involve the joints and those which engage the major shafts are the class which most often are attended with unsatisfactory results, and hence are the subject of malpractice suits. Fractures, when improperly treated or when they occur in those of unsound health, may terminate in (a) non-union, (b) deformity, (c) ankylosis, (d) muscular atrophy, (e) shortening, or (f) gangrene.

Non-union.—There are no means known to art by which we can predict non-union or prevent it in many cases, hence we can not be censured for failure of union when our treatment has been on the right lines.

Deformity.—While, as a rule, particularly in the young, deformity can and should be prevented, in the adult, in certain types of fracture, its suppression is often quite impossible.

Ankylosis.—Muscular ankylosis is a general sequence of all fractures and shortly disappears. Arthritic ankylosis is the phase which most commonly disables the injured and leads to lawsuits. It is well to bear in mind that in the most aggravated types of this the use of the limb and time mainly overcome it—more so, it is true, in certain joints than in others.

Muscular Atrophy.—Atrophic changes in the soft parts follow all fractures; but it is only when muscular wasting is persistent and permanent that complaint is heard. However, it must be a very unusual event as a permanent condition, as I have never seen a case of that trophic disintegration of muscle mentioned in the text-books. As acute temporary atrophy is always a curable affection after fracture, it is quite inconceivable how its presence can be made the pretext for litigation.

Shortening.—Moderate shortening is a usual event in many fractures, hence it is only when the reduction in length is excessive that it can afford a pretext for damages; and even then, with young, restive patients, or those ungovernable to treatment, no fault can attach to the medical attendant.

Gangrene.—But few cases of gangrene have come under

my care in fracture cases—five, as nearly as I can remember, in all. It must be admitted that they all occurred through too tight bandaging. With the exception of one, they occurred under the gypsum bandage.

In all these the limb had to be sacrificed. This is an accident, fortunately, which, while the most deplorable, is the most rare. My impression is that a limb is almost never lost in a simple fracture from gangrene or asphyxiation of the tissue except through ignorance or carelessness on the part of the medical attendant.

In considering the treatment of fracture from a forensic standpoint, a regional division of the body may somewhat simplify our work.

THE UPPER EXTREMITIES.

Shoulder Joint.—Fractures which involve the anatomical neck of the humerus have been mistaken for dislocation; the epiphyseal disc sinks under the deltoid and the shaft is greatly displaced by muscular action.

A violent blow on the shoulder may paralyze the arm, occasion a fracture or dislocation. Only a most careful examination will always enable us to distinguish them.

In any event, if we are in doubt a consultation should be requested and an adjustment applied.

Civil actions seldom arise in consequence of fracture through the center of the humeral shaft, but as we approach the insertion of the digital muscles and the condyloid ridges the case is different.

Elbow Joint.—As the elbow joint is a complicated articulation, any fracture which extends through the condyles and opens the humero-ulnar articulation may be serious in its consequences as far as the future flexibility and strength of the joint are concerned.

A wide difference of opinion yet prevails in the details of treatment of this lesion, so that there remains a wide loophole for escape in the event of suit. Some authors recommend the straight position, the arm extended; others want it flexed, or would have motion begun early; others only after union is effected.

Wrist Joint.—As fractures which occupy the middle of the shafts of the radius and ulna usually unite well under ordinary treatment, with the application of general principles, those which sunder the bone near the radio-carpal articulation may be now considered.

It can not be said that there is a very wide diversity of opinion on the treatment of a typical Colles fracture, probably for the reason that, in spite of any line of treatment adopted, more or less impairment in motion, deformity, and ankylosis remains.

This was my position in an essay last October before the New York State Medical Association; but issue was taken with me, and some went so far as to affirm that by an appropriate therapy good results should be always secured.

Valentine Mott, writing twenty-five years ago on this subject, said, in a communication which was used as testimony in court in a malpractice case (McClelland, *Malpractice*, page 203): "Fractures of the radius anywhere from two or three inches of the wrist joint, even when treated

by eminent surgeons, are often very difficult of management so as to avoid deformity; indeed, more or less deformity may occur under the treatment of the most eminent." Nevertheless, of all joints in the body, there is none, perhaps, in which good or indifferent results are dependent more on treatment in fracture than this. Not that we can make it perfect, but appropriate treatment will avert many unpleasant consequences.

LOWER EXTREMITY.

Fractures, Intracapsular and Extracapsular, in the Hip Joint.—Intracapsular fractures at the hip, as they mostly occur in the old and seldom unite, are not often the subject of civil actions for malpractice. The fragments rarely unite, not because there is any good anatomical reason for failure in this direction, but because it is impossible to rigidly confine the patient in the dorsal decubitus.

Extracapsular fractures are uncommon at the hip and are usually amenable to ordinary treatment.

The battle ground has been in cases of the shaft of the femur. The femur is a difficult bone to manage in fracture. Its powerful muscular envelopes hold the distal fragment in a vicious grip, which is only overcome when dangerous pressure is exercised on the soft parts. Can we secure union here without shortening? Mott again speaks on the subject (*loc. cit.*) in the same case, and says that "more or less shortening is uniformly the result after fracture of the thigh under the most fortunate circumstances." On the same occasion the late Dr. Alfred C. Post stated that the injury of the soft parts would interfere with extension of the limb, and that he had personal knowledge of two cases in which the attempt to make extension and counterextension resulted in mortification and the thighs had to be amputated.

Of late years fracture of the femur has been chiefly treated either by the gypsum cast or by extension, in the United States. Dr. Lewis A. Sayre was a warm partisan of the plaster dressing, alleging almost uniform good results without shortening. He lays the laws down as to the principles of extension, fixation, etc., which are all very well in theory and long known as of fundamental importance in surgery, but which are utterly impracticable in the majority of cases. Dr. Frederick Hyde reported three hundred and eight cases of fracture of the femur, which were treated in Bellevue Hospital from 1868 to 1873, inclusive, in which the average shortening in all cases (the perfect and others) was half an inch.

In the years 1872 and 1873 the late Dr. Frank Hamilton and Dr. Lewis A. Sayre reported their results separately, Sayre employing plaster dressing with almost no shortening, if any. Hamilton's cases were treated with Buck's extension. He confessed to having shortening as a rule. Sayre's tables bear the traces of an enthusiast, for in the column of results there is an apparent evasiveness of detail as to deformity or shortening, while the successes are submitted in detail. (A record of fractures treated at Bellevue Hospital with the plaster apparatus from April, 1871, to April, 1872.)

Dr. Hamilton's tables of results in fracture treatment, revised and completed by McClelland, presented to the

American Medical Association in 1856, though a unique and exhaustive *résumé* of the subject, are of little or no statistical value, for the reason that they are drawn from widely scattered sources and necessarily inaccurate because "of the difference of interpretation in analyzing results." For instance, one author may affirm that he has a perfect result after the fracture of a femoral shaft if his patient showed no lameness. On the contrary, another would fail to realize perfection unless full length were restored. Now, Velpeau taught that there was never any limping when the shortening did not exceed three quarters of an inch (*Leçons sur les fractures*, p. 211).

Liston said that it should be borne in mind that there had been fractured limbs released from splinting at the proper time, of the proper length, free from deformity, which had, nevertheless, soon become bent and shortened (Liston's *Elements of Surgery*, p. 555).

It may then be laid down as a rule that shortening is the common result after fracture of the femoral shaft, and that full restoration of length is the rare exception.

Fracture at the Ankle Joint.—Simple fracture of the tibia or fibula, or both, is of common occurrence; and except in unusual instances, from censurable neglect generally, does not become the subject of malpractice suits. But those oblique fractures in the lower third of the tibia, and that type designated "Pott's," are difficult to treat, and are often followed by deformity and defective joint action, regardless as to how they are managed. I have never seen a genuine Pott's fracture so treated but some deformity remained.

Percival Pott himself, as well as Dupuytren, both distinguished authorities on fracture, regarded fracture of the internal malleolus with fracture at the lower third of the fibula and extensive laceration of ligament and tendon, and dislocation, as always a very serious affair.

Certainly in this, as in all other types of fracture, as a general rule, results will be commensurate with the skilled attention bestowed.

The Question of Dressings and Mechanical Adjustment.

—Of late years a considerable number of practitioners have had to sustain malpractice suits in which the dominant question at issue has had reference to the materials employed and the time at which definite adjustment was made. Since the introduction of plaster of Paris the treatment of fracture has undergone a revolution. That it has greatly simplified its treatment goes without saying; but that its employment is safe and the results are as good as treatment by the older methods is not by any means yet settled. My own experience entirely coincides with that of a modern author, and I am in entire accord with his views. McClelland (*Malpractice Suits*, p. 176) says that "plaster of Paris as a primary dressing requires large experience, inasmuch as it is likely to be followed by the same bad results that so frequently follow the use of the 'primary' or 'initial bandage.' It is not yet the *sine qua non* so long and anxiously looked for by surgeons in the treatment of fracture. The other forms of so-called immovable dressings are just as objectionable for the same reasons. As a secondary dressing, after the primary are removed, and as

a dressing for compound fracture, it is highly satisfactory; and for hospital practice, where it can be seen every few moments and be under the eye of the house surgeon or a nurse familiar with these injuries, it may be employed with good results. The surgeon who applies it to his patient ten or twelve miles away does so at great peril to his patient and himself."

Dr. Lewis A. Sayre and others were warm advocates of *primary* plaster dressings. In my own time of internship, in 1875 and 1876, it was the routine practice to envelop the freshly fractured bone at once on the patient's entrance in wet plaster bandages.

It was a vicious, cruel, and destructive practice; but it was all the rage, and he who neglected to employ it was an "old fogey" or was not up in *progress* (?).

But gangrene so commonly followed ankylosis, shortening, and deformity, that its primary employment is generally discarded now, though it died hard before surgeons would open their eyes to its dangers.

Plaster of Paris brought with it a change in the attitude of the limb, and introduced a new principle of treatment in fracture. With its employment the limb must be extended and the joints locked immovably. The principle of muscular relaxation and postural methods were necessarily cast aside. The old-time fracture box was thrown out as a relic of barbarism. But with these innovations in simple fracture treatment it yet remains an open question whether they have constituted real progress or not. Every individual case of fracture constitutes an entity in itself; therefore to attempt to generalize any form of treatment as applicable to all is worse than folly.

Hence, with the exception of very aggravated and unusual cases, no blame should attach in a given case because certain special details in treatment were not carried out by the medical attendant.

The treatment of fracture in respect to the time of "setting" the bone has been radically changed of late years. In the beginning of the present century and for some time after, it was the common custom to delay splinting the limb for some few days after fracture.

John Hunter taught that splints should not be applied until after all inflammation had subsided (Hunter's *Surgical Lessons*, p. 177), while Chelius advised primary fixed dressing only for oblique fractures and those which involve the collar bone, and directed that for the first three or four days nothing should be done except to lay the limb on a pillow in such a position as will give the patient the greatest ease and soothe the irritable muscles (Chelius, p. 555).

I have recently set forth in an article entitled *At what Date should Permanent Dressing be applied after Fracture?* *Practice*, Richmond, Va., April, 1893, my views on this question, and cited cases which have come to my knowledge in which suits for malpractice have been instituted—in one set in which it was alleged that permanent fixtures had been applied too early, in another in which judgment had been given because the medical attendant had been too tardy in applying rigid fixtures.

The fact is that at the present time the tendency is to

apply permanent fixtures too indiscriminately as a primary measure.

Indeed, there can be scarcely a doubt but that the most disastrous consequences we ever see in fracture most often ensue from rigid, unyielding dressings over the freshly mutilated parts.

It is better, then, to err on the side of safety; wait until the circulation is re-established and all violent inflammatory reaction is passed; then so adjust the limb that the patient will secure the greatest comfort with the best promise of good results. If the doctrine of rigid immobilization would hold, there might be some justification for the immediate adjustment in a permanent fixture of all simple fractures. But it will not, for any one of experience knows that moderate intermittent motion in a fractured limb often rather favors than hinders osseous consolidation.

It is a moot question among many of our most eminent authorities whether, in many types of fracture, any sort of splinting is ever of any service—as in intracapsular at the hip joint and impacted Colles's fracture in old people. From a forensic standpoint it must necessarily be an extremely difficult question to answer in many instances as to just what is the most judicious line of treatment to adopt, which is censurable or which is not, particularly when one must decide without having seen the case, when acting as an expert.

Treatment in Compound Fractures.—So great and rapid have been the advances in the treatment of compound fracture within the last two decades that, when properly managed, now many lives and limbs are spared which were formerly sacrificed, distortions obviated, inflammation, necrosis, tetanus, and mortification prevented. Painless and aseptic skillful manipulation of mangled parts, a more intimate knowledge of pathological changes, with the mechanical aids and perfected dressings at our command, have each and all contributed toward bringing the treatment of compound fractures to well-nigh a state of perfection.

Any tyro of common sense may treat a simple fracture. Handy old men have been efficient "bone setters," but for the intelligent management of compound fractures at the present day special skill is imperative.

Many a smashed, temporarily asphyxiated limb, which in years gone by would be promptly condemned to the amputating knife, must now be saved.

The medical attendant should not only be familiar with all the principles of treatment of these cases in modern times, but he should also be ready to do such osteoplastic operations as the case may require during the progress of repair. To do anything less is an injustice to one's patient, and leaves one open to a civil action.

Statistics tell us that the mortality in the treatment of compound fractures under modern methods has fallen from sixty to less than five per cent.

It may be added that the proportion of limbs spared and made useful is equally large. And along with all this, one of the most salutary and beneficent features is the enormous diminution of human suffering.

The responsibilities of the surgeon in serious com-

pound fractures are always great; therefore, to do full justice to his patient and protect himself, he must redouble his vigilance and throw around his patient and himself such safeguards as will redound to the welfare of both. In the foregoing notes extensive reference to the historical part of the subject has been purposely omitted, my aim having been rather to present what would seem to be the safest lines on which the whole subject of fracture should be regarded when the question of malpractice may arise, and the means which one should employ to protect himself in all cases of this description.

There are fractures of many other bones of the body which often entail lawsuits, particularly those of the skull, clavicle, and ribs, but in the present brief notes it was found impracticable to incorporate them.

Members of our profession, as a rule, should discourage as far as possible suits for malpractice. Without the connivance or encouragement of practitioners their successful prosecution is rarely possible. So that, unless a case presents evidence of positive criminal carelessness or total want of skill, we should not give them our support.

Medical Practice in Belgium.—"By a recent decision of the Belgian Government the applications of foreign medical men desiring to practice in Belgium will first be referred to a special committee to ascertain whether the applicants' scientific attainments are such as to justify the Government in conferring this privilege upon them. This is as it should be, and it would be a wise thing on the part of the French Government if they would exercise a like liberality. The United States boards of health should all of them be vested with like power to discriminate against the hordes of medical pretenders who are flocking to our shores from foreign lands. The Illinois State Board of Health has been dealing efficiently and with measurable success with such incompetent men, and the corresponding boards in all the States would show their wisdom by doing likewise. The action of Belgium is timely and in the right direction."—*North American Practitioner*.

Antidote to Hydrocyanic Acid.—"Since hydrocyanic acid is oxidized to oxamide by hydrogen peroxide, experiments were made by P. Krohl to see if the latter substance could be employed as an antidote in the case of hydrocyanic-acid poisoning. These experiments are reported as successful, the acid, in larger quantity than the fatal dose, having been administered to dogs and cats, and its effects stayed by means of hydrogen peroxide. The experiment could be made daily for weeks together without permanently injuring the animal."—*Druggist's Circular and Chemical Gazette*.

Hydrogen Sulphide as a Poison.—"Lehmann has established by an elaborate investigation that the inhalation of 0.07 to 0.08 per cent. of hydrogen sulphide in the atmosphere produces in the course of a few hours very dangerous symptoms, the presence of 0.1 to 0.15 per cent. causing death quite rapidly; 0.015 per cent. in the air can be inhaled for some hours without detriment, but more than 0.02 per cent. produces injurious effects. The system can not be made to tolerate this gas; on the contrary, it becomes more sensitive upon repeated inhalations. Uchinsky could not find any evidence that the gas acts as a hypnotic, as Schulz states."—*Druggist's Circular and Chemical Gazette*.

Formanilide.—"This newly brought out substance is recommended as being possessed of analgesic and antipyretic properties analogous to those of antipyrine and acetanilide. It occurs in the form of long, flattened, four-sided prisms; melts at 46° C., is readily soluble in alcohol, and somewhat less so in water. A three-per-cent. solution injected subcutaneously produces anesthesia. A twenty-per-cent. solution produces upon the tongue a strong biting sensation at first and then a long-continued numbness. When dusted upon bleeding wounds, formanilide is said to be a much more powerful hemostatic than antipyrine."—*Druggist's Circular and Chemical Gazette*.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, SEPTEMBER 9, 1893.

THE FIRST PAN-AMERICAN MEDICAL CONGRESS.

At the time of our going to press, three of the four days appointed for the sessions of the First Pan-American Medical Congress have passed, and, so far as the reports received at this office enable us to judge, they have been well spent. We feel that we need make no apology for devoting so much space as we do in this issue to an account of the general meeting, deferring our reports of the section work. We give Dr. Pepper's address as president of the congress in full; to condense it or paraphrase it would be to mutilate it. We feel sure that every physician whom this number of the *Journal* reaches will read the address with satisfaction.

It is well that the countries of the Western Hemisphere, among which there is no longer a monarchy, should approach nearer and nearer to community of interest and aspiration. To the accomplishment of such an end nothing could be more conducive than their forming a closer acquaintance with each other, and no initiative in that direction could be more promising than one taken by the medical profession—a profession proverbial for its fraternal spirit. The Washington assemblage of physicians from all parts of North America, Central America, South America, the West Indies, and the Hawaiian Islands may prove more far-reaching for good than would be imagined by one who viewed it simply as part of the machinery in a discussion of medical matters. Our professional brethren who are visiting us from other countries have been attracted hither, we presume to think, quite as much by a desire to come into close personal contact with well-known American physicians as by the expectation of obtaining a large audience for themselves or of forming a part of other men's audiences. This is an honorable and commendable feeling. For the opportunity of gratifying the medical profession of the entire hemisphere is indebted to the secretary general of the congress, Dr. Charles A. L. Reed, of Cincinnati. It was he who conceived the idea of such a gathering, it is to his tact that we owe the official steps that zeal it into being, and his rare carefulness and indefatigable zeal have made it successful. All through, Dr. Reed has been the soul of the undertaking, and he is now fairly entitled to be credited with its success. We hope that many more Pan-American medical congresses will be held, and that they will be managed as cleverly as Dr. Reed has managed this one.

THE LATE DR. JEAN MARTIN CHARCOT.

The life of the great Charcot came to an end unexpectedly, while he was temporarily staying at Morvan, about the middle

of August. Bourneville, a former pupil and colleague of Charcot's, writes in his journal, *Le Progrès médical*, that "death came on suddenly to the great master, and nothing had occurred to enable his friends to forecast such an event." Recent visitors to his clinique at the Salpêtrière had not failed to notice a loss of muscular vigor, a shambling gait at times, and a suggestion was awakened in the minds of many that the nervous and muscular apparatus of the great teacher were no longer so well attuned to one another as formerly. His vigor of mind and intentness of interest in scientific subjects were, however, in no wise abated.

The artistic element in Charcot's character was strong, and, with the qualities he possessed for acute observation and crisp description, helped him to place neurology on the high plane that it occupies to-day. Of his powers as an observer or clinician an editorial writer in the *Lancet* has said: "He is worthy to rank with Trousseau and Laennec." As a delineator or "word painter" he excelled. From the time of his early thesis on chronic pneumonia, about 1860, until his late psychological studies—for during recent years he has been concerned with those subjects rather than with his former problems in neurology—he has had no equal in graphic teaching. His artistic faculty found expression in the *Nouvelle iconographie de la Salpêtrière*, in *Les Démoniaques dans l'art*—by himself with the artist Richer—and in the collection of illustrations adorning the walls of his consulting rooms. These illustrations have for their chief theme the ancient conception of hysterical or epileptic "possession," an imaginative conception largely, on the part of the various artists, but based on facts. Charcot was on the *qui vive* for illustrations in the neurological field, and few teachers have availed themselves more fully than he of the improved processes of photography and other graphic methods. Charcot was great as a pathologist, and he was not hindered by the advance of years from continuing his work in that direction. He was a man of wide general attainments, interested in the sciences outside of medicine, and conversant with the literature of other countries as well as his own. His linguistic attainments were remarkable, as has been demonstrated at many a congress in England and on the continent. His voice will be greatly missed at the Rome Congress in 1894.

In conclusion, to quote again from Bourneville, "Science has lost in Charcot one of her most eminent and most noble representatives; France has lost one of those men who brought her added honor and contributed to her greater reputation through the whole world."

Charcot was born in Paris in 1825; he was therefore not more than sixty-eight years old at the time of his decease. The list of his contributions to medical literature is too great to be enumerated here. He was a member of the Institute of France and of many other societies in his own country and in others.

TYPHOID FEVER IN HARTFORD IN 1891 AND 1892.

The last Report of the State Board of Health of Connecticut contains a paper on Connecticut River Water as a Source of

Typhoid Fever at Hartford, contributed by Dr. Herbert E. Smith, the board's chemist.

The water supply of Hartford is ordinarily ample under a gravity system, feeding a suitable number of storage reservoirs. During a period of seven years, ending in 1891, it was at no time necessary to resort to river water, and the pumps at the river stations have been maintained only for emergencies. In 1891, however, the storage supply ran so low that a part of the city was supplied from the river, notwithstanding the fact that it was known that the river was constantly subject to contamination by sewage from Springfield, Mass., and from other smaller towns north of Hartford.

In the spring of 1892 there was an unusual number of cases of fever, and Dr. Smith was requested to make an investigation in order to learn how far the water supply or other possible sources of the disease had been at fault. The condition of the river water, it may be said, had been a source of more or less apprehension on the part of the consumers. This river water supply, therefore, was properly made the chief subject of inquiry, but attention was also given to the milk supply and the ice supply. These latter were severally excluded as the inquiry progressed, and the river water as a public supply to a part of the city became more and more distinctly incriminated.

The district supplied by river water, being populous and otherwise specially susceptible, had been in previous years more severely visited by fever than other districts. This peculiarity was present, also, to an exaggerated extent in 1892, but the greatest significance was attached to the prevalence of the fever in unusual months and to the fact that those months corresponded with the period of the river supply *plus* an average incubation period. Thus there were more cases of fever during the unusual months, November, December, and January—a period corresponding to the time when cases originating in the use of the suspected supply must have appeared. The reporter rejects the argument as to an epidemic influence possibly existing at that time, on the score that the fever was manifest nowhere else in the State than in Hartford.

The months of November and December, 1892, were marked by a high typhoid-fever mortality—the reported or estimated number of cases not being given for comparison—due to a return to the use of river water during three weeks and a half ending November 18, 1892. This recurrence of fever must be taken as confirmatory of the position assumed in respect to the unusual prevalence of typhoid fever a year before—namely, that the water from the river was a large factor, probably the largest one—along with other factors never wholly absent, in fanning the fever flame in winter.

The reporter takes up the question: Why, if the river water was productive of so many fever cases, were there not even more cases? His reply is important. He states that the sanitary officers of Hartford early and strongly urged the people of the river district to boil the water used for domestic purposes. This advice was very generally followed, it is believed. Furthermore, the river was not grossly polluted at the time of its examination by Dr. Smith, and was probably not very much

worse at the times when it was used as a public source of supply. A large amount of sewage, no doubt, flows into the stream, but the dilution is so very great that the chemical constitution of the water as a whole is not decidedly affected. Although in the latter part of 1891 the contamination was relatively much greater than usual, on account of the low state of the river, still it is not clear that the water contained large amounts of typhoid-fever poison. Our best observers hold the opinion that under conditions such as ruled at Hartford a large proportion of the endangered population will resist the contamination, and that only the more susceptible part will contract the fever.

The source of the typhoid-fever germs was not positively discovered, but the opinion of the reporter is that they came down the river from Springfield, twenty-five miles distant from the point where the Hartford supply is taken in. Cases and deaths had occurred at Springfield in the latter part of 1891, and it can not be doubted that fever germs entered the river and were carried southward. But the investigation was proposed to Dr. Smith at a period when it was too late for him to satisfy himself that the germs of typhoid fever were water-borne over that extent of twenty-five miles in number and virulence adequate to cause the transplantation of the disease from the one city to the other. It is Dr. Smith's belief that this was the manner of causation of the winter cases at Hartford in the river-supplied district.

Dr. Smith feels warranted by his facts in asserting that the Connecticut River just above Hartford is as pure as at any other point in his State, and he remarks that it is unsafe to use its water for drinking at any point in that State. That city is the only one that has hitherto resorted to river water as a public supply, even in emergencies, and the lesson taught by the experiences of the past two years will doubtless prevent the repetition of the experiment at any point within the reach of the influence of the State Board of Health, of which Dr. Smith is a member.

MINOR PARAGRAPHS.

PREPARATIONS OF GOLD.

DR. W. F. BARCLAY writes to the *Brooklyn Medical Journal* for September that he has for three years been experimenting with different preparations of gold. He concludes from his studies that the bromide of gold and arsenic is as useful therapeutically as any other known preparation of gold. Mr. Hays, of Pittsburgh, has made a liquor auri et arsenici tribromidi, of which the standard dose is ten drops. This dose contains one sixteenth of a grain of the arsenic salt and half that amount of the gold salt. The solution has a beautiful red color. The medicine should be administered in about half a wineglassful of water. It agrees well with the stomach and does not tend to produce constipation. The remedy has been used in cephalalgia, epilepsy, and syphilitic mania. Most of the patients have been discharged cured after a month or six weeks of medication. The treatment generally involved three doses daily, and was sometimes ordered to be continued for a time after the patient's discharge. Dr. Barclay has had another gold preparation made for him which contains mercury as well as arsenic. This new

drug is now being tried clinically by him, and he promises to report upon it.

AN ACCOUNT OF BELLEVUE HOSPITAL.

This is the title of an exceedingly handsome volume of nearly four hundred pages, prepared by Dr. Robert J. Carlisle and published by the Society of the Alumni of Bellevue Hospital. More than a hundred pages are devoted to a history of the hospital, embracing the period from the year 1736 to the present time, and most of the remaining pages are occupied with alphabetically and chronologically arranged lists of the medical officers. There are numerous pictorial illustrations, including a number of exterior and interior views of the institution and portraits of Dr. Valentine Mott, Dr. James R. Wood, Dr. Alonzo Clark, Dr. Fordyce Barker, Dr. William H. Van Buren, Dr. Willard Parker, Dr. Austin Flint, Dr. Isaac E. Taylor, Dr. Frank H. Hamilton, Dr. Benjamin W. McCready, Dr. John J. Crane, Dr. Henry B. Sands, Dr. George T. Elliot, and Dr. Edward B. Dalton, the rule apparently having been adopted of giving likenesses only of the dead. The book is one of very great interest and value, and it is creditable alike to the Society of the Alumni and to Dr. Carlisle. Copies of it may be ordered of Dr. Hermann M. Biggs, No. 5 West Fifty-eighth Street. The price is \$3 for the volume bound in cloth, and \$5 bound in half morocco.

A SCARLET-FEVER TOXINE.

Mr. T. J. BOKENHAM and Mr. W. Soltan Fenwick publish in the *British Medical Journal* for August 19th a paper detailing their research on the pathological effects of certain substances derived from the spleen in cases of scarlatina. They conclude that in cases of rapidly fatal scarlatina a morbid product of a proteid nature is formed that can be extracted from the spleen in small quantities. This substance, when introduced into the circulation of an animal, is rapidly excreted by the kidneys, and acting as an irritant to the secreting structure, tends to produce a condition of acute parenchymatous inflammation. Albuminous extract derived from a healthy spleen, and peptic albumoses, when injected into the circulation, never produced such an inflammation of the kidney.

AN ANTI-TUBERCULOSIS LEAGUE.

FROM the *Union médicale's* account of the proceedings of the recent Tuberculosis Congress we learn that M. Armaingault reported upon the progress of his *ligue contre la tuberculose*. It seems that the league has 2,103 adherents, and that disinfection services have been organized in Arcachon, Nice, Menton, Hyères, and other winter resorts for consumptives. One great difficulty that the league has met with appears to be its powerlessness to enforce the disinfection of hotel apartments; another is that there are still physicians who do not hesitate to proclaim that phthisis is not contagious.

ITEMS, ETC.

Society Meetings for the Coming Week:

MONDAY, *September 11th*: Boston Society for Medical Improvement; Gynecological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

TUESDAY, *September 12th*: New York Medical Union (private); Medical Societies of the Counties of Chemung (quarterly)—Elmira and Rensselaer, N. Y.; Newark, N. J., and Trenton (private), N. J., Medical Associations; Northwestern Medical Society of Philadel-

phia; Baltimore Gynecological and Obstetrical Society; Richmond, Va., Academy of Medicine and Surgery.

WEDNESDAY, *September 13th*: New York Pathological Society; Metropolitan Medical Society (private); Medical Societies of the Counties of Albany and Montgomery (quarterly), N. Y.; Worcester, Mass., District Medical Society (Worcester); Philadelphia County Medical Society.

THURSDAY, *September 14th*: Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y.; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

FRIDAY, *September 15th*: Baltimore Clinical Society; Chicago Gynecological Society.

SATURDAY, *September 16th*: Clinical Society of the New York Post-graduate Medical School and Hospital.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 5, 1893:

DISEASES.	Week ending Aug. 29.		Week ending Sept. 5.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	0	0
Typhoid fever.....	37	8	19	7
Scarlet fever.....	34	2	23	2
Cerebro-spinal meningitis....	2	2	74	0
Measles.....	66	6	50	2
Diphtheria.....	98	27	3	9
Small-pox.....	2	0	7	0

The Health of Dr. Lewis A. Sayre.—We are glad to be able to say that an operation for cataract recently performed on one of Dr. Sayre's eyes has proved most successful, and that his general health is excellent.

Proceedings of Societies.

FIRST PAN-AMERICAN MEDICAL CONGRESS.

Held in Washington on Tuesday, Wednesday, Thursday, and Friday, September 5, 6, 7, and 8, 1893.

The President, Dr. WILLIAM PEPPER, of Philadelphia, in the Chair.

Opening of the Proceedings by the President of the United States.—A joint resolution was unanimously adopted by the Senate on June 3, 1892, concurred in by the House of Representatives on July 14, 1892, and approved in July, 1892, by which the President was authorized and requested to invite the several Governments of the Western Hemisphere to send official delegates to a Pan-American Medical Congress.

PRESIDENT CLEVELAND, in opening the proceedings of this great assemblage at Albaugh's Opera House, spoke as follows:

"The part assigned me on this occasion admits of few words. It, however, affords me the opportunity to say how pleased I am to be in any way related to an assemblage such as this, called together in furtherance of the highest and noblest purposes and desires. I hope I may also be permitted to add that the protection of the public health and the prevention of contagious diseases are objects properly brought under consideration at the capital of a nation which appreciates fully the serious importance of everything which aids in making intercourse between civilized countries and commerce between them safe and easy. It is also fitting that those who devote themselves to saving human life and the alleviation of human suffer-

ing should consider the modes of reaching these beneficent ends at the seat of a government whose greatest regard is the welfare and happiness of the individual citizen. It only remains for me to declare this Pan-American Medical Congress open for the transaction of the business which has called it together."

An Address of Welcome on behalf of the District of Columbia.—The Hon. J. W. Ross, President of the District Board of Commissioners, delivered the following address:

The District of Columbia has entertained many distinguished public gatherings, but it has never known such a one as that which I now have the honor, in the name of the local municipality, to welcome to the national capital. For the first time in the history of the New World there are assembled in one of its capitals representatives of one of the oldest and most honored of the learned professions from all the Americas. It is fitting that in the District which derived its name from that of the great discoverer, and that in the year set apart as the one in which the nations may do honor to his memory, the Governments whose existence was hastened by the results of his genius and daring should send their representatives to a Pan-American convention.

It is in keeping also with the spirit of the age which has prompted this gathering of representative men that the delegates so convened should meet not for individual or national aggrandizement, but for the loftier purpose of extending the range of medical knowledge, and for the alleviation of human suffering throughout the world.

To a profession as progressive as that of medicine and surgery the results of such a conference can not be overestimated. When we consider the vast area of the surface of the globe here represented, the infinite variety of racial characteristics, of climatic conditions, and of all environments affecting health and disease, we can understand that such interchange of observation and experience was never before made possible. What may not be accomplished by all of the forceful men from all the Governments here represented, by plans for the establishment and for the enforcement of international quarantine regulations, and for international co-operation against the spread of infectious and contagious disease! The municipal authorities in many of the cities of the United States are now endeavoring to locate hospitals for the treatment of contagious diseases near enough to the centers of population to avoid the dangers incident to a long transportation of patients affected with such diseases, and near enough to be within the range of a water supply and of adequate sewerage facilities. It is the common experience of all who are charged with such responsibility that the dread occasioned to those who reside in the vicinity of the proposed locations assumes almost the proportions of a panic.

If the position maintained by many eminent physicians be correct, that such hospitals if properly conducted are not likely to be the means of communicating disease to those residing near them, the public mind should be relieved of its needless apprehension, and if this great body of experts should deem the matter worthy of its consideration there can be no doubt that an authoritative expression of its views would do more than could be hoped for from any other source to educate the public mind upon this subject. May there be as the result of all of your deliberations not only the formation and the renewal of personal friendships, but also a wider knowledge, a higher inspiration, and a just conception of the demands of the age upon your profession. And I can not but believe that this extraordinary spectacle, this assemblage of physicians from all of the great powers of the Western Hemisphere, has a deeper significance than even that most laudable purpose of the extension of medical knowledge among its constituents. Does it not indicate that benevolence and philanthropy are no longer lim-

ited by national boundaries, but that they are becoming as broad and universal as humanity itself?

There will never be a time when there will be no clashing of interests among the nations of the earth. But when the poor of Ireland were suffering for want of bread, when Chicago was desolated by fire, when Charleston and Johnstown were helpless, and when the peasantry of Russia were starving, the world's sympathy in the form of material aid ignored the ocean's barrier and the boundaries of States, directed only by the thought that the stricken and the suffering belonged to the same great human family. These bonds of human sympathy and the new swift means of intercommunication are bringing the nations into closer relationship. May we not be encouraged to believe that this Pan-American convention is a forerunner of successive congresses of all civilized States, whereby the common interests of the race may be fostered and maintained?

Mr. President and gentlemen, while you will have as your immediate hosts all of the members of the local profession, who are our most honored and respected citizens, I beg to assure you that the entire people of our District deem themselves honored by your choice of our city as your place of meeting, and that all will endeavor by word and act to make your welcome to the capital so cordial that you may carry with you to your distant homes only pleasant and agreeable recollections of your great convention at Washington.

The Secretary General of the Congress.—The President, Dr. PEPPER, in calling upon Dr. Charles A. L. Reed, of Cincinnati, for a report, alluded informally to the gratitude felt by the congress toward Dr. Reed for the zeal and industry he had brought to bear in furthering the successful issue of the undertaking.

Dr. REED said that the congress as it then stood must constitute his report. The work of organization had doubtless been an exacting, but nevertheless an extremely pleasant, task. After tracing the various steps which had been followed in working out the great scheme to its final point of perfection, he said that the medical profession of the Western Hemisphere had responded with enthusiasm. The delegates would represent every medical society in a profession numbering one hundred and fifty thousand.

Dr. S. S. ADAMS, of Washington, the Chairman of the Committee of Arrangements, then detailed the various plans for the entertainment of the delegates.

The remainder of the work of the opening session consisted of speeches of reciprocally congratulatory character by delegates on behalf of the constituent countries and colonies represented.

The President's Address.—Dr. WILLIAM PEPPER, of Philadelphia, the President of the Congress, delivered in Metzerott Hall the following address:

GENTLEMEN OF THE FIRST PAN-AMERICAN MEDICAL CONGRESS: This occasion is a unique one, and the thoughts which force themselves on the minds of all of us are, I am convinced, so similar that the briefest greeting might well seem the most fitting address. But when I reflect that I stand here to represent the original committee appointed in pursuance of the resolution which was adopted unanimously on May 5, 1891, at the meeting of the American Medical Association, and that this resolution extended a cordial invitation to the medical profession of the Western Hemisphere to assemble here in a congress, I realize the unusual dignity of the duty I must discharge. If anything could add to the dignity of this assemblage, which for the first time asserts formally the organic union of the physicians of all America, it is the fact that the Congress of the United States, impressed with the importance of our proposed meeting, passed a joint resolution (July 18, 1892), requesting

the President to extend those invitations in response to which we welcome the presence here of official delegates from all the Governments of the Western Hemisphere. In like manner are the several States of our own Union, the principal municipalities, and many of the leading educational institutions, both of North and South America, represented officially. You will not, then, think it strange that, called upon to address such an assemblage in this Columbian year, it should seem less fitting to dwell upon any technical topic than to turn our thoughts to the state of this continent and of its aboriginal inhabitants at the time of its discovery by Columbus, and to the obstacles which opposed him and the great men who completed his work. For these have had a bearing on the racial developments which have since occurred here, and should be held in mind in any estimate of the progress we have made during the subsequent four centuries. The state of medical science in Europe at the time of the discovery, and the spirit which has controlled its subsequent course, are fitly to be studied in connection with what we have accomplished during the same period and with the opportunities which present themselves to us at this time.

The recognition of the appropriateness and importance of this great meeting has been immediate and universal. International although it is, the basis of its organization and the special features which mark it, remove all possible suspicion of an imitation of, or of interference with, the great International Congress whose successive meetings form a crescendo scale of scientific and administrative triumphs which the medical profession of the world regards with justifiable pride.

Our executive committee, and our efficient general secretary, to whose unselfish energy and masterly powers of organization we owe a great debt of gratitude, studiously avoided the possibility of any such interference by delaying the selection of a date for our meeting until that of the Congress at Rome was announced, and by then adopting a date which not only permitted but encouraged the presence later at Rome of those who should gather here. I can only add my deep regrets that the unhappy reappearance of cholera in southern Europe—striking example as it is of the urgent importance of the very work which calls us together—has necessitated a postponement until next spring—a postponement which, however, there is no reason to fear will lessen the complete success of the meeting on its newly announced date. The International Medical Congress is, indeed, a splendid demonstration of the solidarity of the profession and of the world-wide scope of the objects we pursue.

This congress represents much more, however, than our common interest in medical science and the common feeling of brotherhood which animates the entire profession. It is—indeed, it always has been, and forever may it so continue—the glory of the medical profession that their allegiance is one and undivided, for their service is solely in the cause of truth and humanity. Dynasties have risen and crumbled; the map of the world has been changed times almost without number, but the march of medical science through the ages has been ever onward and upward toward those lofty goals—the prevention of disease, the relief of suffering, the improvement of the race.

For us who meet here there is all of this glorious recollection and animating purpose, and there is much more to unite and to inspire us. We meet under the shadow of giant conceptions, as old as Aristotle, which agitated the minds of the great thinkers of antiquity, and were but slowly approaching a definite form when the sublime faith and genius of Columbus solved the problem of the globe.

It is true that this vast American continent, with its sixteen million five hundred thousand square miles of territory, already numbers one hundred and ten millions of inhabitants,

embracing all types of human life, and many varieties of political organization. But all that has yet been accomplished is but the feeble beginning of the development which awaits us. When Canning secured the recognition of the republics of South America, he boasted that he had called the New World into existence to redress the balance of the Old, and yet the luminous suggestions of Franklin, of Bolivar, and of Blaine as to the political and commercial relations of the countries of the Western Hemisphere are still only prophecies which must long await their fulfillment.

The destinies of nations are slowly evolved, and occurrences which fill the horizon of a generation appear to the broad gaze of history as mere features in the great panorama of the ages.

Even a period of four hundred years is but a fraction of the history of Spain, of France, of England. Yet four hundred years ago this entire continent was not only undiscovered and unknown, but its very existence was unsuspected save in the ingenious speculation of philosophers. We recall the familiar but ever interesting lines of Seneca:

Venient annis secula seris
Quibus Oceanus vincula rerum
Laxet, et ingens pateat tellus,
Tiphys que novos detegat orbes
Nec sit terris ultima Thule—

and do not marvel that their strain of glowing conviction should have led Columbus to write them out twice over in his *Profecias*. But all the same, this New World lay shrouded in the obscurity of the great Sea of Darkness, out off, as we have since learned, from the known inhabited world by changes wrought in remote geologic eras, and waiting the fullness of time which should lead the inspired genius of Christopher Columbus to seek the East by sailing west. We now know that in his quest of a western passage to Asia he reached the eastern shore of this continent on October 12, 1492, but even to the time of his death, on January 20, 1506, neither did Columbus nor any voyager or writer have any conception of the vastness and real significance of his discovery. All that the geographical knowledge of the day enabled them to grasp was the belief that Columbus had found a new route to the Indies by sailing west. Within a few years, however, the daring sailors of Spain and Portugal, of Italy, and of England, pushed their voyages along the coasts. The astonishing discoveries of Americus Vesputius on his celebrated third voyage in 1501–1502, when between Lisbon and the island of South Georgia he traversed an arc of ninety-three degrees, led him to apply for the first time to this continent (it really was South America of which he spoke) the title of New World (*Mundus Novus*). It concerns us not to consider further how, by no intent or design of Vesputius, portions of South America at first, and later the entire continent, came after his death to be named after him. Yet when a few days ago I held in my hands the little quarto published in 1507, in which Professor Martin Waldseemüller, of the College of Saint Dié in Lorraine, first suggests the name America, in utter ignorance that the coast explored by Vesputius was continuous with or even related to the land discovered by Columbus, I could not help smiling sadly at the frantic and fruitless efforts we make to secure immortality by our petty observations, while here Fame, in strange whimsey, threw her laurels for the greatest discovery ever made around the head of one who neither had nor preferred a claim to it.

Geology and paleontology have taught us that this so-called New World is in reality, in a scientific sense, better entitled to the name of the Old World. The oldest known strata have their widest development on its surface, and animals, such as

the horse, which are said to have been introduced after 1492, are shown to have had their original habitat here and to have migrated hence to Europe, so that Cortes and Pizarro only re-introduced them to their former home. It is more important to recall the fact that the entire stretch of North and South America was, at that date, 1492, peopled more or less thickly with the descendants of tribes who had resided here from very remote antiquity. A high authority assures us that the number of these aborigines was probably from twelve to fifteen millions, and in spite of considerable differences in physical appearance, as between the Iroquois of New York and the Aztecs of Mexico or the Incas of Peru in dialect and habits, it is generally conceded that this vast aboriginal population, of North America and South America alike, with the exception of the Eskimos, belonged to one great race of red men.

Eskimos and red men alike seem to have migrated to our continent at one time, or more probably in successive waves, in the remote past, either when the northwest corner of America was joined to Siberia by the elevation of the area now known as Bering Sea, or when the lofty submarine ridge which now passes from France to Greenland was elevated so that it would be possible to travel on foot from Europe to America. If the attempt be made to decide at what period of geologic time such immigration occurred, and whether in one great migration or, as seems most probable, in successive waves, problems of extreme if not insurmountable difficulty present themselves.

The aborigines who were living on this continent at the time of its discovery by Columbus presented, it is true, considerable differences in the stage of development they had reached, as well as in their language and even in their appearance. There are long intervals of social development evident between the squalid sty of the California savage, the log house of the Iroquois, and the great structures of Zuni, of Tlascala, or of Uxmal. Yet in them all can be demonstrated an underlying principle of adaptation to a certain mode of communal life such as all American aborigines are believed to have practiced. All attempts to distinguish the existence of special races, as of the mound-builders, have broken down in the light of critical study, and the powerful arguments of philology confirm the results of zoological study as to the essential unity of the American red race. The tribes in different parts of this vast territory certainly presented marked differences in physical appearance, and our ethnological collections show that as regards size and weight of frame and shape of skull considerable variety existed among them. But all possessed the cinnamon-colored or copper-colored complexion, the high cheekbones and small, deep-set eyes, the straight, black hair, with scanty or absent beard; and the conclusion of the most competent authorities is that no sufficient differences—physical, linguistic, or social—existed to invalidate the evidence in favor of the unity of the race.

Fortunately we are not called on to attempt to read the geological record. For our purpose it is indifferent whether all the relics of the ancient Americans are of the neolithic type, or whether the apparently plausible claim be ultimately established that palæolithic remains are also found in various places. This at least we know, that the soil and climate had shown themselves favorable to the development of a population already numerous, vigorous, hardy, and enduring, and brave and warlike, though often cruel, and evidently advancing in social development, though at very different rates at different localities. Ignorant as we are of their primitive origin, it is doubtful if the most earnest advocate of the monogenist view that all mankind was originally descended from one pair, will urge that our aborigines were descended from a single couple, or even from a

few boat-loads of Asiatics accidentally carried to our Pacific coast, or that we shall hear again the arguments drawn from the many striking resemblances between the myths, languages, customs, or hand-wrought objects of the aboriginal Americans and of various Oriental nations. The surprise which, I am sure, all of us have experienced at these resemblances must be checked by these two thoughts so well expressed by Fiske and by Lubbock respectively, that one of the most important lessons impressed on us by a long study of comparative mythology is that human minds in different parts of the world, but under the influence of similar circumstances, develop similar ideas and clothe them in similar forms of expression; and again, that different races in similar stages of development often present more features of resemblance to one another than the same race does to itself in different stages of its history.

An immense amount of sympathy has been expended upon the cruel treatment of the American aborigines by the European invaders. Of course, it was the sad old story, so often repeated, whenever a better armed and more highly civilized power has come into conflict with a primitive, ignorant, and ill-armed people. Over the ghastly picture of Indian slavery one would indeed wish to draw a veil, though its darkest shadows are relieved by the splendor of the character and labors of the illustrious Las Casas, and by the enlightened action of those great men, Emperor Charles V, Pope Paul III, and Cardinal Ximenes. But it is a romantic extravagance to deplore the destruction of any system of government or society which existed in 1492 in any part of the continent. If the present state of the native Indian population in North and South America is far from satisfactory, and fails to fulfill the promise shown, especially in South America during the first century after the conquest, may this not fairly be attributed to unwise legislation by the ruling nations, to the absence of continued, effective religious instruction, and to the base cupidity which has led us to promote the fatal passion for stimulants, so common among barbarous people? There seems no sufficient evidence to make us lose hope that the remains of the aboriginal Americans may, under more wise and equitable treatment, gradually develop into useful citizens of our republics, and be capable of wholesome assimilation with the body of the population.

It is easy to assert and hard to disprove that the development of the red race on this continent was progressing slowly prior to 1492. As a matter of fact, we do not possess the data, either about their early history or about the primitive condition and rate of development of any of the more civilized races, to permit us to institute a comparison. Our earliest knowledge of the ancient Egyptians, for instance, reveals them living in a state of civilization already advanced at least a full ethnical period beyond that even of the Aztecs. How many centuries had elapsed while the successive stages of savagery and barbarism were passing in Egypt can never be even surmised. There seems no reason to doubt that, had America not yet been discovered, there would have been going on here for the last four hundred years a slow and irregular approach to a higher social condition. There certainly is no doubt that during and since the conquest many sad mistakes, and not a few atrocious crimes, have been perpetrated in the name of civilization and of liberty. But, on the whole, the student of history is forced to admit the enormous advantages which have resulted from the conquest by Europeans of the fifteenth and sixteenth centuries of tribes the most advanced of which were still in a very primitive state of civilization.

I have ventured upon this rapid sketch of a familiar subject because it is well that we should be clear in our comprehension of the conditions which existed in America four hundred years ago, when the start was made to introduce the European races

and civilizations. We meet here to-day to represent what these have accomplished in their new environment during these four centuries in regard to certain highly important subjects. We can not fail to be interested in considering what scientific acquisitions in these branches were actually brought here, what disadvantages were to be contended with, how far our progress may be regarded as satisfactory, what great questions there are which concern us all deeply, and in what lines of research and work we may unite for the common good, and for the greater advancement of science.

The words graven on the tomb of Ferdinand Columbus in the cathedral at Seville: "To Castille and Leon, Columbus gave a New World," are indeed true, but they do not express the whole truth. John Fiske well says: "The discovery of America may be regarded in one sense as a unique event, but it must likewise be regarded as a long and multifarious process. The unique event was the crossing of the Sea of Darkness in 1492, and no ingenuity of argument can take from Columbus and from Spain the glory of an achievement which has, and can have, no parallel in the whole career of mankind. It established a true and permanent contact between the eastern and western halves of our planet, and brought together the two streams of human life that had flowed in separate channels ever since the glacial period." But to demonstrate the magnitude of this discovery, to determine the physical features of this Western Hemisphere, to plant firmly the seeds of European civilization, demanded the heroic exertions of two full centuries. Not Spain alone, but Portugal, Italy, France, England, Holland, Denmark, Russia, played their part, and the names of Cabral and Pinzon and Magellan, of Cortes, Balboa, and Pizarro, of Ponce de Leon and Soto, of Champlain and La Salle, of Drake, Hudson, Baffin, Davis, and Bering, must remain associated forever with this stupendous and progressive work of discovery. Not until 1806 was the last step taken by Lewis and Clark, who then succeeded in crossing the continent of North America from east to west, and thus completed the task undertaken by Champlain in 1608. And if the mere study of the outlines and dimensions of America occupied two centuries, what are we to say of the far greater obstacles opposed to the colonization of the vast territory, and to the determination and establishment of suitable forms of government, and of harmonious relations between the numerous States and countries into which America soon came to be divided?

The older political systems of Europe seem to require still the assistance of considerable artificial support, and their occasional disturbances are of a decidedly unpleasant character. Is it strange that some of us still have our little unpleasantnesses at home or with our neighbors, which indicate that the education of our people is as yet woefully imperfect in those things that most nearly concern their welfare? Of this, at least, we may be sure, that all that promotes free intercourse among us helps on mightily the solution of these hard problems. It is a true saying that to know is to excuse, and, more than this, in regard to nations if not strictly in regard to individuals, it may be added that to know is to love. We turn with quickened interest to the sage advice of the illustrious Franklin, who, in 1749, embodied in his plan for the organization of the University of Pennsylvania an earnest advocacy of the thorough teaching of the Spanish and Portuguese tongues as likely to hasten the development of those close reciprocal relations which he foresaw would inevitably arise between the countries of the two Americas. The spirit of the age as it embodies itself in our educational systems and in our literature, the giant

forces of steam and electricity, as they link together the most distant points of our territory, are working inevitably together for the enlightenment, the elevation, the better mutual understanding, and the more cordial relations of all of us.

The year whose four hundredth anniversary we now celebrate found the world stirred as never before. A work of tremendous importance for the future of the human race had been going on amid the gloom of what are often called the dark ages. The more closely this period of absorbing interest is studied the more do we appreciate the magnitude and the necessity of the changes effected during those centuries in preparation for the splendid activities of the Renaissance. The mission of the middle ages had been really, though not obviously, a cosmopolitan one, and it was fitting that the noblest achievement of the Renaissance should be the discovery of America. The barriers between nations had been lowered, and there had been going on the process of blending and interpenetration which was soon to be extended to this Western Hemisphere with such large results. The protest against mere dogma in religion and in philosophy, the revolt against usurped and abused absolutism, the demand for light and knowledge and the common rights of humanity, these awakened then to be stifled no more, but to swell forever in larger utterance until they shall, in some yet distant golden time, announce universal liberty under equitable laws and universal peace through arbitration. It is not for us to taunt the glowing expectations of the men of 1492 with their long-postponed fulfillment. It ill becomes us of to-day to speak in other than tones of humility when across the brightest spots of the vaunted civilization of the close of the nineteenth century after Christ there still fall so many dark shadows lingering from the deep mediæval night.

How each generation turns aside with the restless impatience of children from the lessons of the past, and shuts its eyes to the truth which inexorable history calmly shows, that long periods of time are required for the accomplishment of each great advance in religious, or political, or social, or scientific truth.

Yet though we smile somewhat sadly as we read the bursts of enthusiasm so plentiful at that time, we dare not challenge the fitness of that grand name, the Renaissance, to the age which, through its mighty discoveries and the master minds who used them, diffused among the nations the new conceptions of the earth and the skies, of the Church and the State. Only the pity of it that such long centuries of travail must ensue between this implanting of the seed of religious and political liberty and the mature growth for which we still wait.

In no respect may the discovery of America be regarded as the dividing line between the middle ages and the modern era more truly than in regard to medical science. In spite of the prodigious learning of the most distinguished Arabian and Jewish physicians, such as Avicenna, the Prince of Physicians, of Albucasis, of Avenzoar, the Wise and Illustrious, of Maimonides, their medical science was far too largely speculative and philosophic. Great universities were established, some of which, as those of Bagdad and of Cordova, possessed regal revenues and magnificent libraries. Numerous hospitals were founded, of which the large and wealthy one established at Cairo in 1283 merits special mention. But the outcome of this long dominion of the Arabs and the Moors, so far as concerns medical science, was merely a marked advance in chemistry and pharmacy, the introduction of many new remedies, and the advocacy of the union of the natural sciences with medicine. Their chemistry was tintured strongly with alchemy, their clinical teaching was elementary, their diagnosis and treatment lacked the true Hippocratic force and directness.

* Á Castilla y á Leon
Nuevo mundo dió Colon.

The endless speculations and metaphysical discussions of the schools had shown that it was not that way true progress lay. Unaided observation had scarcely gone further in eighteen hundred years than the point to which the immortal Hippocrates had carried it. True medical science, which could not progress without precise methods and instruments of precision, was forced to wait until from very different quarters came the development of the natural sciences and the era of exact experimentation which alone rendered them possible. Harvey's immortal discovery of the circulation of the blood was not announced until 1616, and his almost equally important and epoch-making discovery of the origin of the higher animals from the egg was published in 1651; yet it may be safely asserted that the work of this modest and truly scientific Englishman did more to advance medicine than all the labors of all the schools from the days of Hippocrates. Not only were the facts demonstrated of infinite importance, but his method of patient, exact observation and experimentation until the truth was developed by cautious induction marks the introduction of a new era, and stamps Harvey as the father of modern medicine.

Galileo first indicated the use of the thermometer in medicine about 1595. Sagredo, of Venice, improved it in 1613, and Sanctorius, in 1625, urged its importance in the study of disease forcibly, but as yet ineffectually. Just as the astronomer, Galileo, gave us the first rude thermometer, Kepler, another illustrious astronomer, gave, in 1604, the first record of an accurate count of the human pulse. But so slowly did the importance of this datum in the study of disease impress the medical profession that the acute Sydenham, who lived until 1689, nowhere mentions a single pulse count. It is hard to find anything which illustrates better the radical difference between the spirit of mediæval and of modern medicine than the vast mass of obsolete literature upon the pulse, loaded with fanciful speculation and super-refined subtleties of description, and yet wholly deficient in the only features which would give practical value to the study. What progress in exact medicine could be made without chemistry? Yet scarce any development in this branch occurred between the eighth and seventeenth centuries. And it was Boyle, the father of modern chemistry (not born until 1627—died 1691), who first succeeded in freeing from the trammels of alchemy this noble science. Not until the end of the seventeenth century did the value of quantitative analysis begin to be appreciated. Lastly, it was not until 1590 that we hear of the first compound microscope in the hands of Jansen.

Meanwhile the gross superstitions, combined with a blind dependence on the great authorities of antiquity, and especially on Aristotle and Galen, which had so long dominated medical science, yielded slowly to the growing light of positive knowledge. Fine-spun subtleties, drawn from metaphysical speculation; the fantastic notions of alchemy and astrology; the rank growth of impostures which flourished in the soil of ignorance, and the bigotry which placed every organ under the charge of a special saint and conjoined with every remedy a special form of supplication, still marked medical teaching and medical practice. But the bold, fearless, investigating spirit of the sixteenth century did its work for medicine as it did for other great matters. Vesalius (1514-'64) and his contemporaries created accurate anatomy. Paré (1509-'90) stamped imperishably on surgery the influence of his genius and lofty character. Paracelsus (1493-1541) hurled the shafts of ridicule and invective against the groveling subserviency to ancient authority, and did a rough but important stroke of work toward the emancipation of the medical mind. The grand old Hippocratic method of careful observation and cautious reasoning was reasserted, the unproductive philosophy of Galen and his Arabian

worshippers was discarded, and at last there begins to emerge from the darkness of so many centuries modern medicine, the medicine of loyalty to Nature and revolt against mere human authority; of reverent skepticism and reasonable faith; the medicine of scientific experimentation and of humane vivisection, that insists upon knowing the causes of disease and that looks to Hygiene as its noblest expression.

The history of European medicine for more than three hundred years is a record of which we may well be proud, when the enormous obstacles to progress are held in view. It is not necessary to remind this audience of a single one of its great triumphs. Vesalius and Paré, Harvey and Sydenham, connect themselves with Bichat and Laennec, and Hunter and Jenner, and Pasteur and Lister, and Virchow and Koch, and the torch of genius is passed down the line of these immortals and lights up the ages with the splendor of their achievements. But it is sad to reflect upon what has been done as contrasted with what might have been. The dense ignorance of rulers and masses on scientific questions, the slow progress of sound, useful education among the people, the huge claims of imperialism and militarism, the wanton waste of luxury, have retarded research, have left but paltry sums available for the diffusion of knowledge, have hindered the embodiment in legislation and in actuality of much that would help the healing of the nations. It is an odd commentary on the vaunted civilization of to-day to contrast the sums doled out by the most enlightened governments of Europe for the promotion of higher education and original research or for the suppression of preventable diseases with those lavished on the vast hosts of armed men and the huge fleets of unwieldy armored ships deemed necessary for the maintenance of peace and order.

Within our own day we have seen the announcement of the grandest generalization reached by the human mind, in this century at least, and advanced in the most philosophic and inoffensive manner, received with a burst of intellectual skepticism and of religious intolerance which showed that the old forces against which the Renaissance protested, and still protests, are yet alive, though happily shorn of most of their power. The marvelously rapid spread of the illuminating doctrines of Darwin, and their incorporation in the thought and speech of the world, and in the teachings of the churches, may indeed be pointed to as the crowning intellectual achievement of the nineteenth century.

If the actual progress of medical science was slow in Europe during the years which followed that *annus mirabilis*, 1492, surely no word of reproach may be uttered against the early settlers in North and South America, because, amidst their heroic efforts to conquer this vast continent, it was long before they found time or energy to devote to the cultivation of that practical and essential subject of medical science. It is true that in 1551 Charles V founded the University of Lima, in Peru, and in 1558 the University of Mexico. Yet it does not appear that medicine was taught at these universities until a little prior to 1700.

In North America, although Harvard College was founded in 1636, the title of university seems to have first been applied to the University of Pennsylvania, which in 1765 established the first school of medicine in the United States. The scattered handfuls of early settlers on our shores had indeed problems facing them more urgent than the promotion of science. They differed as widely in their motives for undertaking the appalling task of conquering and colonizing America, and in their fitness for the work, as they did in their nationalities. Separated widely from the mother countries, hampered very often by unwise and vexatious interference from the home governments, they waged war against the powerful tribes of aborigines who

swarmed over the country, and against the no less serious obstacles of untried climatic and political conditions. Bloody warfare raged promiscuously, and disease was rife. We have seen that the work of mere preliminary exploration occupied two centuries. The close of the third century found the early struggles approaching a successful ending, only to be followed by violent political changes, not accomplished save by long and costly wars. The English conquest of Canada in 1759-'60, the achievement of independence by the United States in 1783, the establishment of the independence of the South American Republics in 1810 and the ensuing twenty years—these are the events from which the future historian will date the Renaissance or the Decadence in America, and to which reference will always be made in estimating our capacity for progress in politics, in literature, in art, and in science.

For a long time it seemed even to friendly critics that the new races which strove for a foothold on American soil were unlikely to thrive as vigorously as in their accustomed habitats, and the impossibility of developing a genuine and lasting American type was freely asserted. To those of us who have considered this point with anxious care, the last two decades have brought results that put to rest all apprehension. Whatever may be the future changes in the political organization or relations of the countries composing America, it is a demonstrated fact that the European race in America, which already numbers over a hundred millions, will show no decline in vigor or in energy, in physical or in mental strength. It is not on account of mere bigness in material achievement that we point to the millions who fought in the great civil war; or to the hundred and seventy thousand miles of railroad in the United States—almost as much as in all the world besides—and the \$10,000,000,000 of capital invested, and the army of nine hundred thousand employees; or to that tremendous structure, the Canadian Pacific Railroad; or to the plans now under consideration for developing a continuous railway system for the entire continent, from Montreal or Puget's Sound to Buenos Ayres. It is, even more, as evidences of large imagination, of courageous resolution and dauntless tenacity of purpose, and of enormous power of physical endurance that we value the enterprises which have subjugated this continent so swiftly and are hastening its commercial consolidation. We may be assured that countries which have shown such sturdy love of independence and resistance to outside interference, which have displayed so much sagacity in adapting their political constitutions to their peculiar conditions, which liberate and enfranchise all who dwell within their limits and afford to all an equal chance of advancement, will work out their destinies to far larger and wiser plans of friendly co-operation than we can now foresee.

Turgot, in his memorable address in the Sorbonne, well declared, "Tous les âges sont enchaînés par une suite de causes et d'effets qui lient l'état du monde à tous ceux que l'ont précédé." The discovery of America depended on the operation of causes which can be traced back many centuries. The present condition of our continent, four hundred years later, is the result of the action and reaction of mighty movements which involve every country of the world. Here is the new and probably the last great place of gathering and intermixture of all nations. Here as nowhere else are to be studied with all the aids of exact science the problems of ethnology and sociology. Here are to be worked out to the best advantage the problems concerning the relations of man to his physical environment; and the demonstration that, in spite of the apparent magnitude of the powers of Nature, and in spite of the admitted influence of climate and physical condition upon the progress of civilization, the powers of man for intellectual and social advancement are incalculably superior.

In all of this work a large share must devolve upon medical men, and fortunately our position in America is one which will enable us to work together with good effect. The high average intelligence of our people will make them prompt to appreciate results of solid utility or scientific value. The enormous wealth, present and prospective, of this continent should readily be diverted more and more bountifully to the promotion of learning and research—if, as may be trusted, we shall strive more and more after peace among ourselves and abroad.

We shall never cease to be proud of our lineage, or to acknowledge the immense debt we owe to Europe. Its languages are ours; its glorious past is part of our heritage; its mighty names in art and philosophy and science are household words with us. Its rapidly advancing civilization incites us to loftier efforts. But the balance between the Old and the New Worlds is being redressed.

All know how the examples of our young and vigorous communities have supplied and fed the infectious principles of political liberty and of social equality. In every struggle for the rights of man, from the terrible but beneficent drama of the French Revolution down to the present hour, our example and our assistance have been invoked.

I can not detain you by an enumeration of the services already rendered by America to medical science. Almost immediately after the discovery important contributions to pharmacology were announced, chiefly from South America, and from the introduction of guaiacum, in 1508, until now these contributions have become more and more frequent. The entire medical world was agitated during the latter half of the seventeenth century by the struggle over the merits of cinchona bark, introduced into Europe in 1640 by Juan del Vego, and no more convincing tribute can be adduced as to the value of medical and sanitary science than the prominent place occupied by malarial diseases in the general and medical literature of the seventeenth and eighteenth centuries as contrasted with the feeling of impunity with which they are now regarded. Among the results which may be anticipated from this meeting is, I trust, the adoption of some well-considered plan for systematic conjoint study of our American remedies and their pharmaceutical preparations, looking to their scientific classification, to greater uniformity in their preparation, and ultimately to a single pharmacopoeia for the entire continent.

The introduction of nitrous oxide (1844) and of ether (1846) into medical practice, with which the names of Wells and of Morton are so honorably connected; the establishment of the operation of ovariectomy by McDowell, of Kentucky, upon a secure scientific basis—these and hundreds of other achievements of lesser brilliance are too familiar to need mention. Every one knows now how superfluous it is to say a word in defense of American literature, and certainly we who know how powerfully the opinions and practice of medical men in Europe and throughout the world are influenced by American writings may view our position with some complacency. Yet a survey of what America is actually contributing to medical literature shows clearly how far we are behind the nations which lead in medical thought. In the year 1879 Rupprecht's *Bibliotheca* gave as the total number of new medical books, excluding pamphlets, periodicals, and transactions, 419, divided as follows, viz.: France, 187; Germany, 110; England, 43; Italy, 32; United States, 21; all others, 26; and for 1891 I find the same *Bibliotheca* gives the total number as 1,063, divided as follows, viz.: Germany, 360; France, 243; Great Britain, 141; United States, 80; Italy, 78; Austro-Hungary, 70; Spain, 24; other countries (chiefly Switzerland and Denmark), 67.

On the other hand, in the more ephemeral forms of medical literature the figures are very different. I have had a careful count made of the volumes of medical journals and transactions filed in the library of the Army Medical Museum at Washington, with their respective places of publication, and from this it is clear that of these classes of medical literature there were, in 1890 and in 1891, published in America (including Canada, the United States, and Latin America) about twice as many volumes as in Germany or France, and fully three times as many as in Great Britain.

Of course we must not forget the fact that in the hurry of our life of to-day many observations and investigations of great value are published in journals, instead of being reserved to become part of more serious and complete volumes. But it will not be doubted, I think, that the great excess of medical journals in America, as contrasted with the comparatively small number of new medical works, is entirely consistent with the admitted leadership of Germany, France, and Great Britain in medical science. The fact that during the past twelve years Germany has risen from a place in this list second to France, 110 as against 187 in 1879, to the first place at present, with 360 new medical works in 1891 as against 243 published in France, speaks eloquently of the strenuous effort with which newly united Germany is straining forward in science as in other fields. The truth is that the apparently extraordinary number of medical journals in America is due chiefly to a substantial reason, and one which influences equally the existence of very numerous medical schools and medical societies. The vast extent of territory and the relatively sparse population render it impossible to serve the country with as low an average of medical men, schools, societies, or journals as is possible in more densely populated countries. As to other and less satisfactory reasons which have operated, especially in the United States, to produce a great growth of ill-equipped medical schools and of poorly supported medical journals it is not necessary to speak here. Indeed, the rapid rise in the standard of scientific requirements, both of medical men and medical literature, and the increasing appreciation on all sides of the fact that the higher medical education is the true interest both of the profession and of the public, is accomplishing the much-needed work of checking the ill-considered establishment of new medical enterprises, and of stimulating those in existence to more earnest life and more lofty aims.

So true is this in regard to our medical journals in particular, that no one who has occasion to consult regularly the files of any number of them can fail to have been struck forcibly with the steady and decided improvement in the tone of their management and in the scientific quality of their contents.

This congress meets at a period of peculiar and critical interest in medical education, and I am glad to say that for the first time in the medical history of the United States we may feel proud to have such a meeting convened here, and to invite a close examination of our educational standards and facilities. I should fail in courtesy and in candor alike were I not to acknowledge the great value of the example which has been so consistently set by Latin America and by Canada in the maintenance of a high standard of qualifications for medical practitioners.

Fifteen years ago the medical profession of the United States arraigned severely the management of their over-numerous medical schools.* While Canada then exacted a reasonably strict entrance examination and a course of medical study ex-

tending over four years, with one session of six months in each year, and while every country in Latin America exacted a collegiate degree or a rigid entrance examination, and a course of medical study extending over six years, it was the general custom with the medical schools of the United States to grant a diploma conveying the full right to practice medicine to applicants who had been admitted without preliminary examination, and had attended without term examinations two courses of lectures covering about five months, and had passed a single and final examination conducted by their own teachers, whose emoluments were derived solely from the fees of such students. This discreditable prostitution of a great educational trust had been gradually brought about by large causes upon which I may not now comment. But it is with justifiable pride that we may point to the admirable and sweeping reforms that have since been instituted. It remains true that the laws of many of the States allow charters for medical schools to be secured without any guarantee of the standard of education that shall be maintained. But the awakened sentiment of the profession and of the community has in a rapidly increasing number of the States insisted that medical graduates before being admitted to practice shall pass a State examination conducted by an impartial board of examiners appointed by the Governor. The medical schools, to their honor be it proclaimed, have, with few exceptions, been foremost in the struggle to secure this wise and beneficent legislation. They have done much more. In advance of these laws which will insure a far higher standard of medical qualifications in the States fortunate enough to be so protected, the faculties of a number of the leading schools have forced their standard up at first to three years of obligatory study, and now to four years of eight months' study each, with a carefully graded curriculum and with strict examinations before entrance, at the close of each term, and finally before graduation.

When we recall that this has been done without the slightest governmental aid, and, further, that, owing to the prevalent view that medical schools have been sources of large profit to their faculties, the streams of private benefaction had not yet been directed in their favor, you will appreciate the high sense of duty and the devotion to science which have led these faculties to assume greatly increased labors with an expectation of considerably diminished remuneration owing to reduced attendance of students and to augmented expenditures.

The Committee of Arrangements of this congress has wisely provided for a tour of inspection of some of these institutions. It is trusted that all of our foreign delegates, and as many as possible of the members of this congress, will avail themselves of this opportunity to examine the equipment of some of our leading medical schools. They will be gratified to find in hospitals, in laboratories, and in libraries and museums alike, facilities which bear comparison with those of Europe. They will find an arrangement of studies, and, above all, an organization for the conduct of daily thorough bedside instruction in all branches of medicine, which leave little to be desired. It is easy to foresee, as another of the desirable results of such meetings as this held successively in various parts of America, such increased acquaintance with and confidence in our respective methods of medical education and medical treatment as will retain on our continent many of our students and many of our invalids who have been in the habit of going farther to fare no better.

A broad field opens before us for the study, with the aid of collective investigation, of the distribution and course of phthisis and rheumatism and other important diseases as influenced by race and locality. The endemic fevers, other than malarial and typhoid and yellow fever, which are said to prevail in various

* Regular schools, 65; homœopathic, 11; eclectic, 4; total, 80, in 1877.

parts of North and South America, have long demanded systematic investigation to complete the study which the illustrious Drake began. We shall now have the opportunity of studying, equally by means of collective investigation, the relative effects of various climates on the numerous races now represented in America, and of determining more accurately the scientific and practical questions connected with our extensive series of health resorts which embrace the finest examples of every type. There are, indeed, none of the sections provided for in this congress from whose work more valuable results should follow than from those on medical pedagogies, on hygiene and climatology, and on quarantine. It was a sense of the urgent importance of these latter subjects, especially at the present time, and of the valuable results sure to follow their consideration by such a body as this, which led the Government of the United States to extend the cordial invitation which has been uniformly accepted on the part of the Pan-American Governments. I feel that by this action there has been secured for the subject of Hygiene and State Preventive Medicine a formal recognition never before accorded on this continent, and one which must surely be followed by the willingness of the respective Governments to use their influence to secure the enactment and efficient administration of proper legislation in accordance with the recommendations of this body of eminent experts.

When the International Medical Congress met in Philadelphia in 1876, the address on Hygiene and Preventive Medicine, delivered by the distinguished Bowditch, himself a pioneer in sanitary science, was one of the most impressive utterances on that important occasion. The review there given of the work of the previous century in this country in sanitary science was not flattering, but with the fine enthusiasm which marked that gifted man he predicted the immediate opening of the grandest epoch yet seen in the history of medicine. His closing appeal must be quoted: "Our PRESENT DUTY is organization, national, State, municipal, and village. From the highest place in the national council down to the smallest village board of health we need organization. With these organizations we can study and often prevent disease." These stirring words were in accord with the spirit of the times and with the developments of science. When the brilliant discoveries of Koch brought to light the specific bacillus of tuberculosis and of cholera, and pointed out the scientific method to be pursued in similar investigations in the future, an unanswerable argument was provided against skepticism or indifference or official penuriousness. It required courage and showed rare breadth of view in Lord Palmerston to issue his celebrated reply to the Presbytery of Edinburgh on the occasion of the threatened outbreak of cholera in 1853, in which he urged that the weal or woe of mankind so far depends upon the observance or neglect of the natural laws by which the affairs of the world are regulated, that if the local causes of disease were not removed before the return of the hot weather, the pestilence would be sure to return in spite of all the prayers and fastings of a united but inactive nation.

Much was accomplished, it is true, in preventive medicine between 1853 and 1876, when Bowditch spoke; but it is scarcely an exaggeration to say that the progress in the past twenty years has been greater than in the preceding twenty centuries. We have not, indeed, yet detected the specific poison of every infectious disease; even in regard to the familiar and much studied yellow fever, the latest publication of the distinguished Surgeon General of the United States Army shows that this point is still unsettled. But the position of the whole matter is changed radically. Hypotheses have given way to facts. Every one now knows, or ought to know, that the most dreadful diseases are inseparably connected with definite organisms, that these organisms have special laws of development and distribu-

tion, that to destroy or exclude them is to avoid the disease, and that to tolerate conditions which favor their development is to encourage and invite the attack of the disease. When these simple, demonstrable propositions are considered in connection with such scourges as cholera and yellow fever, and typhus and typhoid fever, and scarlatina and diphtheria, and epidemic meningitis, it needs no further argument to prove the value and the necessity of quarantine, and of efficient medical inspection and protection. Nor does it need further argument to show the wisdom of establishing laboratories of hygiene at many points over the country, of equipping them amply with the ablest men and the finest apparatus, and of endowing them liberally, so that the search after the yet unknown causes of disease, and after the best methods to prevent the development of such causes as are known, may be prosecuted with ceaseless vigor.

It is easy now to get a hearing for these views when public comfort is disturbed, the public purse threatened, and the public conscience awake and sensitive. At this moment our great commercial communities are reposing in confidence upon the sanitary measures adopted by our Governments, in accordance with medical advice, for the restriction and exclusion of two dreaded pestilences, cholera and yellow fever. Recall with me the popular terror of last summer. Recall the hideous loss of life and the disastrous effects on commerce caused by former invasions of these diseases when the communities afflicted were smaller and less wealthy than are ours at present. We do not have to seek back to the middle ages for pictures of desolation wrought by infectious disease. Recall that tragic story of the great yellow-fever epidemic in Philadelphia just one hundred years ago, as told by Rush. Try to estimate the result if cholera had effected a lodgment in New York city in July, 1892, and having found favoring local and climatic conditions, had, as on former occasions, spread its deadly germs to the North and South and West. The fair White City that was rising by that distant lake, under the magic wands of Art and Industry, would have been stricken with a fatal blow. No computation can well exceed the loss that would have fallen on this country. The entire people gazed with bated breath at the struggle waging in New York Harbor, and universal thanksgiving arose when the dread invader was finally repulsed by the vigorous and sustained efforts of the sanitary authorities. That we in America are not to-day witnessing the aggravated recurrence of the epidemic, in accordance with unvarying precedent, can be due only to the continuance of these same efforts, re-enforced with large authority, and aided by more efficient local sanitation. When this gratifying result is associated with the success which for some years has attended our efforts for the exclusion of yellow fever, no further argument can be needed to urge the adoption of such uniform measures as will for the future afford most sure protection against these diseases. These instances exhibit in the most striking manner the need and the value of the international sanitary agreements this congress may do much to promote. But there will occur to all of us many other important questions to be solved only by earnest and united work. Nor can this work be accomplished until Bowditch's cry for organization is far more fully answered than it yet has been. Nothing but organization and co-operation, and, yet more, the establishment in the government of every civilized nation of a department of public health, will secure the continuous and forcible attention which the magnitude of this enterprise demands. There should be, and the day can not be far distant when there shall be, in the cabinet of every government here represented, a secretary of public health, of rank, influence, and prerogative equal to that of any other cabinet officer.

Here, then, is the last and greatest service to be rendered to science and to the nation by our congress. Our combined influence will be irresistible when used in advocacy of higher education; in carrying out large plans for the scientific study of our national life, as affected by social and climatic influences; in the adoption of remedies and remedial measures of demonstrated merit, and in the insistence upon a fuller recognition of the lofty function of preventive medicine. "Salus sanitasque reipublica, suprema lex." Let us acquire here a closer touch with each other, a deeper faith in our profession and its noble destiny, and a stronger determination to labor in brotherly co-operation for the loftiest ideals of service to science and the race.

(To be continued.)

Book Notices.

The Law of Cremation. An Outline of the Law relating to Cremation, Ancient and Modern, together with the Rules and Regulations of Various Cremation Societies at Home and Abroad. By AUBREY RICHARDSON, Solicitor. London: Reeves & Turner, 1893. Pp. iv-187.

THE author of this little volume states that he prepared it from material collected to determine whether a person could arrange for himself as to the mode of the disposal of his remains after death, and whether or not such disposal was entirely in the hands of his executors. It would, at first thought, seem odd that a law must be enacted by which a testator could insure that his body after death would be disposed of according to his own wishes, but further consideration recalls many familiar instances in which a testator's wishes have been thwarted where specific law did not exist.

The ancient law of Egypt, Persia, China, India, Greece, Rome, America, and Judæa is summarized, and the modern law in various European and American countries is reviewed in a succinct and satisfactory manner.

The book will be found useful by any one desiring information on this important subject.

Decipherment of Blurred Finger Prints. By FRANCIS GALTON, F.R.S., etc. London: Macmillan & Co., 1893. Pp. 18. [Supplementary Chapter to *Finger Prints*.]

THIS little volume constitutes a supplementary chapter to the author's monograph on *Finger Prints*, and contains his comments upon a comparison of the impressions of the forefinger and middle finger of the right hand of eight different persons, made in the first instance in the year 1878 and secondly in 1892. The illustrations in the volume afford new evidence of the persistence of the forks, islands, and inclosures found in the capillary ridges.

Indigestion, Gout, Corpulency, and Constipation, clearly Explained, Treated, and Dieted. By THOMAS DUTTON, M.D. Univ. Duhr., Member of the Royal College of Physicians of Edinburgh, etc. Third Edition, enlarged and revised. London: Henry Kimpton, 1893. Pp. x-220.

THIS is a work intended to enlighten the public, and incidentally the profession, on the physiology of digestion and the causes, symptoms, and treatment of indigestion, with a brief reference to foods and the rearing of infants. We believe that the book is well calculated to impress a suffering public with the author's skill, and that its judicious circulation is calculated to increase his practice.

BOOKS, ETC., RECEIVED.

Annual of the Universal Medical Sciences. A Yearly Report of the Progress of the General Sanitary Sciences throughout the World. Edited by Charles E. Sajous, M.D., and Seventy Associate Editors, assisted by over Two Hundred Corresponding Editors, Collaborators, and Correspondents. Illustrated with Chromo-lithographs, Engravings, and Maps. Vols. I, II, III, IV, and V. New York and London: The F. A. Davis Company, 1893.

On the Nature and Treatment of Talipes Equino-varus or Clubfoot. By Bernard E. Brodhurst, F.R.C.S., Surgeon to the Royal Orthopaedic Hospital, etc. London: J. & A. Churchill, 1893. Pp. 60.

Transactions of the New York State Medical Association for the Year 1892. Vol. IX. Edited for the Association by Ogden C. Ludlow, M.D.

The Epileptic Interval; its Phenomena and their Importance as a Guide to Treatment. By William Browning, Ph.B., M.D., Brooklyn. [Reprinted from the *Journal of Nervous and Mental Disease*.]

Symmetrical Localized Hyperplasias of the Subcutaneous Fat. By Albert S. Adler, M.D., San Francisco. [Reprinted from the *Pacific Medical Journal*.]

The Profession of Medicine as sketched from the Outside and from the Inside. By S. W. Kelley, M.D., Cleveland, Ohio. [Reprinted from the *Cleveland Medical Gazette*.]

Unilateral Hypertrophy of the Face. By D. W. Montgomery, M.D. [Reprinted from the *Medical News*.]

Cæsarean Section: Historical, Statistical, and Clinical. By Hamilton Fisk Biggar, M.D., LL.D., Cleveland, Ohio.

Zymotic Diseases in Chicago. Sanitary Exhibit of the Illinois State Board of Health. World's Columbian Exposition, 1893.

Archives of the Cincinnati College of Medicine and Surgery. Vol. I. [Reprinted from the *Cincinnati Medical Journal*.]

Reports on the Progress of Medicine.

PHARMACOLOGY AND THERAPEUTICS.

By H. A. GRIFFIN, M.D.

The Uses of Thioicamf.—Duffey (*Dublin Journal of Medical Science*, May, 1893) has been led to use thioicamf as an intestinal antiseptic, a surgical application, and an antiparasitic in cutaneous affections. His communication has already been briefly alluded to in this journal. Thioicamf is described by Professor Emerson Reynolds, its discoverer, as a "liquid which results when sulphur-dioxide gas is brought in contact with camphor." In this liquid are dissolved several substances destructive of bacteria, among them benzoic acid and phellandrene. Thioicamf can be preserved without pressure in bottles at ordinary temperatures, but on its exposure in thin layers a steady evolution of large volumes of sulphur-dioxide gas charged with the vapors of other disinfectants takes place. From this action it has been much used for atmospheric disinfection, and, for the same reason, Duffey has applied it to the uses noted. For internal administration it was combined with pure butter fat in the proportion of ten per cent. of thioicamf. Of this, ten grains were given in capsule every two or three hours for four doses. The capsules were sometimes coated with keratin, that they might pass through the stomach and be dissolved in the

intestines. The drug was thus used in a case of typhoid fever, in a case of phthisis in which the patient was suffering from pyrosis, in a case of dilatation of the stomach, and in a case of alcoholic peripheral neuritis in which the patient had fetid alvine evacuations. In all of these the signs of fermentation became less marked and the character of the movements improved.

In two cases of scabies a four-per-cent. solution in olive oil effected rapid cures. In bedsores and unhealthy ulcerations it was used in oily solution (four to six per cent.) with the effect of quickly removing fœtor, diminishing the discharge, and promoting healing. No ill effect was noted in any case.

The Treatment of Malignant Tumors by Inoculations of Erysipelas.—Coley (*Am. Jour. of the Med. Sci.*, May, 1893) offers and tabulates "all the reported cases of carcinoma and sarcoma, in which erysipelas, either spontaneous or artificial, intervened," presents several cases of his own so treated, and reaches the following conclusions: 1. The curative effect of erysipelas upon malignant tumors is an established fact. 2. The action upon sarcoma is more powerful than upon carcinoma, in about the ratio of three to one. 3. The treatment of inoperable malignant tumors by repeated inoculations of erysipelas is both practicable and unattended with great risk. 4. The curative action is systemic, and probably due chiefly to the toxic products of the streptococcus, which products may be isolated and used without producing erysipelas. 5. This method should not be employed indiscriminately until further experiments have proved its limitations.

Albuminate of Iron.—Stewart (*American Therapist*, March 15, 1893), though he objects to the statement that albuminate of iron should be given in preference to all other iron salts, because it is ready for absorption without chemical change, and bases his objection on the facts that other salts of iron are absorbed and fulfill their special functions, yet finds much to be said in its favor. Its advantages are that it is not astringent, does not injure the teeth, does not constipate, does not precipitate the digestive ferments, does not irritate the stomach, is readily assimilated, can be given to children with ease, is not toxic, and "fulfills every indication for a plain tonic. It can not be used in place of other salts of iron employed for their astringent or local effect." A favorite practice of the author's is to give, after each meal and at bedtime, a compressed tablet consisting of two grains of iron albuminate and a sixtieth of a grain each of arsenious acid and strychnine sulphate.

Benzonaphthol.—Huchard (*Rev. de pharm.*, February, 1893; *Am. Jour. of Pharm.*, May, 1893) prefers benzonaphthol as an intestinal antiseptic to salol or betol, because it is scarcely toxic and because he thereby avoids the possible dangerous effects of salicylic acid. Three hundred grains of benzonaphthol and seventy-five grains of powdered charcoal are mixed and divided into thirty capsules, of which from six to eight are given in a day.

The Treatment of Diphtheria with Pilocarpine.—Hirschfeld (*Australasian Med. Gazette*, April, 1893) has had an extensive experience in the use of this drug in diphtheria and is much impressed by its usefulness. He explained its action as assisting in the detachment of the false membrane by means of the salivation produced, as causing an increased flow of blood to the parts, and hence a greater number of leucocytes to resist the invading bacilli, and as producing intense perspiration, whereby the ptomaines and toxalbumins already absorbed are eliminated. For a child six years old he orders a mixture of a third of a grain of pilocarpine, from half an ounce to an ounce of brandy, an ounce of syrup of orange, and enough water to make three ounces. Of this a teaspoonful is to be given every two hours. This, as a rule, is sufficient, but, if necessary, it may be given every hour. The brandy is given to counteract

any depression resulting from the pilocarpine. The use of the drug should not be discontinued abruptly. With the production of perspiration the temperature falls and the false membrane is cast off "in a surprisingly quick time." A gargle of chlorate of potassium is also generally employed, together with a moist compress to the throat.

Kumyss as a Food.—Nitchevoff (*N. Y. Therapeutic Review*, April, May, June, 1893) calls attention to the advantages of kumyss as a food and tonic in gastro-intestinal diseases and in fevers, and thinks it often preferable to milk on account of its being predigested by the ferments and its containing tonic principles produced in its preparation. Recent analyses of different kinds of kumyss have shown many species of bacteria present which were not necessary for the production of fermentation, and the author points out the danger of using such specimens, both because they soon become so offensive in odor and taste as to be unfit for use, and because of the danger of the presence of pathogenic germs. Kumyss to be good "must undergo several weeks' fermentation, during which lactic acid, carbonic acid gas, and alcohol are formed" and the casein is partially digested. Properly made, kumyss can be kept for a long time, and it is only such kumyss that may safely be given.

Unusual Tolerance of Nitroglycerin.—Reading (*Therap. Gaz.*, May, 1893) reports a case of chronic interstitial nephritis in which he prescribed nitroglycerin in dose of a hundredth of a grain. This produced the physiological effect, but soon the dose required increasing, as no effect followed its administration. As each increase in dose produced its effect but for a short time, the amount was gradually increased until, in less than a year from the time when it was first administered, the patient was taking a teaspoonful of a ten-per-cent. solution (six grains of the pure drug) at a dose, and with only good effect, for under its use the patient's condition had markedly improved. The drug was given largely diluted to prevent injury from so concentrated a solution. The reporter regards this case as evidence that the good effects of nitroglycerin can be obtained only when its use is pushed to the limit of tolerance, regardless of the size of the dose.

The Therapeutic uses of Exalgine.—Younger (*Lancet*, April 8, 1893) finds exalgine of great service in neuralgic pains of a functional nature, one or two doses producing relief, often permanent. In neuralgic symptoms occurring in the course of mental disease, too, the drug has been most efficient in his hands. In one case of epilepsy, where it had been given for severe frontal headache, not only was that symptom relieved, but the seizures were rendered much less frequent. The doses used were never larger than two grains every four hours, and usually one grain repeated several times daily was employed. The dose was generally dissolved in ten minims of spirit of chloroform, and water or some infusion added to make up the ounce.

Ointment Bases.—Shoemaker (*Medical News*, April 29, 1893) reviews and discusses the various ointment bases, and concludes that in the majority of cases our choice must rest upon lard or lanolin. Petroleum jelly resists chemical change and is pleasant in appearance, free from smell, and of good consistence; but it is apt to be contaminated with irritant impurities, and its absorptibility is slight. Lard is readily absorbable, but readily undergoes decomposition. This, however, may be prevented by adding benzoil or a small quantity of beta naphthol. Suet may be preferred to lard on account of its greater stiffness; it is not, however, so readily absorbed. It may be mixed with lard to produce greater firmness. Lanolin is almost devoid of odor, very rapidly absorbed, aseptic, and unalterable. Spermaceti and cacao butter have the disadvantage of being of unstable composition.

Miscellany.

The Naval Medical School.—We have before mentioned the plan for the instruction of newly appointed assistant surgeons. On June 22d the Secretary of the Navy issued Circular No. 52, as follows:

1. The Naval Laboratory at New York shall hereafter be known as the U. S. Naval Laboratory and Department of Instruction.

2. Assistant surgeons shall, immediately after admission to the navy, be ordered to the Naval Laboratory and Department of Instruction for such study and instruction, under prescribed rules and regulations, as may be necessary to familiarize them with the duties of medical officers afloat and on shore.

Appended to the circular were the following rules and regulations:

I.—Assistant surgeons, as soon as commissioned, will be ordered to said establishment and will be required to faithfully perform their duties while undergoing instruction. They will also be furnished with a copy of this circular, and their names registered in accordance with prescribed form contained in book supplied by the Bureau of Medicine and Surgery. This book will be kept on file in the Department of Instruction for future reference.

II.—The course of instruction will continue for a period of at least three months, and will embrace the following subjects:

1. Chemistry, general, analytical, and organic. 2. Hygiene and sanitary science. 3. Microscopy and microbiology. 4. Military surgery and operative work. 5. Clinical medicine and hospital work. 6. Construction and ventilation of modern war ships. 7. Examination of recruits and life-saving methods. 8. Navy regulations, navy ration, hospital fund, pension fund. 9. Keeping medical records at hospitals and on board vessels of war, and blank forms pertaining to the Bureau of Medicine and Surgery.

III.—The director in charge of the U. S. Naval Laboratory and Department of Instruction will assign assistant surgeons to the Naval Hospital, New York, for careful and thorough instruction in the following branches:

CLINICAL MEDICINE AND HOSPITAL WORK: Bedside examination of patients, visiting hospital with medical staff at morning visit, studying and investigating carefully the etiology of disease, as associated with naval life, and the diseases to which sailors are chiefly susceptible, giving attention to and becoming familiar with the technique of the laryngoscope, ophthalmoscope, practice with trial lenses in helping to determine the nature and degree of errors of refraction, thermometer, stethoscope and sphygmograph, preparation of temperature charts, diet lists, etc., as aids to accurate diagnosis, etc.

NAVY REGULATIONS, NAVY RATION, HOSPITAL FUND, PENSION FUND: *Navy Ration.*—General history of diets, including steps leading to the present recognized principles; general considerations in relation to health and disease, efficiency of force and mortality in time of war; diseases depending upon dietetic deficiencies, with the historical accounts relating thereto; origin of the United States Navy ration, original component parts, with the nutritive and dynamic values and changes at various times, with the effect on values; a study of present United States Navy ration in all relations, including comparisons in nutritive and dynamic values with the rations of foreign navies, and considerations in connection with work done in different climates and parts of ship; spirit ration; condiments; tea and coffee; packing and preserving methods.

Pension Fund.—When established; acts of Congress relating thereto; trustee of pension fund; amount of pension fund; how invested; those entitled to benefit of fund; sources of income to pension fund.

Hospital Fund.—Sources from which derived, and how utilized.

KEEPING MEDICAL RECORDS AT HOSPITALS AND ON BOARD VESSELS OF WAR, AND BLANK FORMS PERTAINING TO BUREAU OF MEDICINE AND SURGERY: Preparation of medical records, embracing all steps necessary to the admission and discharge of patients from hospital, hospital tickets, case papers, reports of medical survey, etc.; also observing carefully the therapeutical indications in each case, general pharmacy, triturations, post-mortem examinations and reports, meteorological observations and reports.

IV.—He will assign Assistant Surgeons to the Naval Medical Examining Board for careful and thorough instruction in the following branches:

HYGIENE AND SANITARY SCIENCE: Embracing the general principles of hygiene, causes of disease, methods of investigation and prevention, vital statistics, first aid to the injured, blood circulation, muscles, exercise, nervous system, contagious diseases, digestion, respiration, organization and duties of health authorities, sanitary jurisprudence.

Water Supply.—Rainfall, flow of streams, storage of water; quantity required for cities and towns, asylums, hospitals, etc.; impurities of water, their origin and nature, whether occurring at its source, in storage, or in distribution, and methods of purification by screens, filter beds, infiltration galleries, chemical processes, etc.; analysis, microscopical and chemical.

Air.—Composition, its impurities, effect of these on the sanitary condition of cities and towns, hospitals, asylums, public and private dwellings.

Soil.—Methods of studying the topographical and geological features of a district in reference to the effect of the quality and characteristics of the soil upon drainage and other sanitary conditions; the location of cemeteries, etc.

House Drainage.—Water supply and drainage of naval hospital buildings and private dwellings; the removal of laundry, sink, and closet refuse; practical elements of plumbing.

Sewage.—Removal and disposal by various methods, including the frequent and systematic removal from cesspools and privies, accompanied by disinfection and deodorization, by the water-carriage system, pneumatic system, etc., to points of its final disposition; the construction of sewers, including combined and separate systems, outfalls, sea outfalls, tank sewers, ventilation of sewers, etc.; final disposition of sewage, garbage, and other refuse by cremation furnaces, irrigation, filtration, chemical precipitation.

Ventilation.—Quantity of air required under various conditions; method of supplying or renewing air by natural or spontaneous means, by artificial means.

Heating.—The various means of heating, by stoves, hot-air furnaces, hot water and steam, and the most practical and efficient treatment of problems arising under various circumstances connected with public and private buildings; the construction of apparatus and the distribution of heat, whether in connection with or independent of the ventilation; the principles of heat and thermo-dynamics, applicable to all constructions connected with heating and ventilation, including boilers, radiators, flow of air through conductors, etc.

Inspections.—Methods of examination of sanitary conditions of public buildings and dwellings at navy yards and stations, and of sewers, drains, and water courses; methods of disposal of sewage and garbage.

Drainage.—The drainage of districts for sanitary objects, surface, and subsoil drainage; drainage of sites for hospitals, dwellings, barns, and outhouses.

Sanitation of Government Reservations.—The construction, care, and management of cesspools, privies, etc., and their disposition with regard to wells and dwellings, care of gardens and yards, with reference to the accumulation and removal of refuse; system of drainage at Navy Yard and Naval Hospital grounds, New York.

Pollution of Streams.—Remedies to be adopted and means of prevention.

Quarantine and Sanitary Regulations.—International, national, State, and interstate quarantine laws; the various measures to be instituted before the departure of vessels from foreign and infected ports; thorough inspection of every part of the ship by medical officer assigned to this duty; medical examination of passengers and crew.

Sanitary Precautions at Sea.—Arrangements and facilities for disinfecting and fumigating ships.

Sanitary precautions to be observed on arriving in port.

Location, character, and construction of quarantine hospitals.

Quarantine regulations with reference to disposal, fumigation, and disinfection of merchandise.

Sanitary administration.

MILITARY SURGERY AND OPERATIVE WORK: Duties of the naval surgeon in relation to care of surgical instruments; carriage of sick and wounded on shore, afloat, embarking, and disembarking, including extemporary transport; preparation for service on board and on shore before action; instruments and supplies in action, and duties afloat and in the various lines of surgical assistance; establishment of field, temporary, and permanent hospitals and lines of assistance; hospital attendants; diagnosis, prognosis, and treatment in full of all injuries in battle, including full instruction in abdominal surgery for wounds; the trephine, amputation, resection, and other operations, and the use of extemporary appliances; preparation and record of statistics relative to the systematic arrangement and classification of the wounded. Construction and study of ambulances of modern design.

CONSTRUCTION AND VENTILATION OF MODERN SHIPS OF WAR: Study of sectional plans of modern vessels of war, showing system of ventilation, heating, lighting, sanitary fittings, arrangement of quarters, manner of berthing officers and men, air space, location of sick bays, dispensaries, storerooms, lavatories, bathrooms, etc.; list of ships of the navy, displacement, type, station, or condition; personal visits of inspection to all ships at navy yard, including receiving ship, vessels in commission, ships of war undergoing construction and nearing completion.

EXAMINATION OF RECRUITS AND LIFE-SAVING METHODS: Will include general inspection of surface of recruit, extremities and articulations, thorax, abdomen, groin and genitals, spine and perineum, head, face, and neck, cranium and organs of special sense, intelligence and age. In the preparation of "list of persons examined" (Form X), the directions embodied in the Book of Instructions will be strictly followed. Rules for restoring the apparently drowned—how to arouse the patient; to expel water, etc., from the stomach and chest; to produce breathing; after-treatment (externally and internally); evidences of vitality, etc.

V.—He will assign assistant surgeons to the Naval Laboratory for instruction in the following practical work:

CHEMISTRY: GENERAL, ANALYTICAL, AND ORGANIC: Inorganic chemistry; also chemistry of air, water, artificial illumination, photography, lime, mortars and cements, building stones, decay and prevention, timber and its preservation, pigments, paints, essential oils, varnishes, explosives, gunpowder, gun cotton, and nitroglycerin. Disinfectants for hospital and ship use. Metric system of weights; qualitative, quantitative, and blowpipe analysis; organic chemistry, general principles and methods of analysis.

Analytical: Qualitative.—Having acquired a thorough experimental knowledge of the reactions of a group of bases or acids, single members of the group or mixtures must be submitted to him for identification, enabling him to proceed from simple to complex cases, until he is able to determine the composition of the most difficult mixtures.

Quantitative.—1. To analyze substances of known composition, such as crystallized salts, that the accuracy of his work may be tested by a comparison of his results with the true percentages.

2. Required to make analyses of materials occurring in commerce or in the applications of technical and sanitary chemistry, etc., as fertilizers, fuel, water, etc. The object being to instruct in analytical methods.

Organic.—The laboratory work to consist of: Ultimate analyses, including determination of carbon, hydrogen, nitrogen, sulphur, and haloid elements in organic substances; determination of vapor densities, molecular weights, specific gravities, melting and boiling points, and calculations of formulæ. Analysis must be made on material supplied or authorized beforehand by the instructor at the laboratory, and he will require of the student, whenever practicable, reports in writing on completion of the work.

MICROSCOPY AND MICROBIOLOGY: Practical acquaintance with the handling of the microscope, its construction, use, care, and choice; simple lens, optical principle, construction, and use; compound lens, low-power objectives, use and care; accessory apparatus, general method of work, illumination, effect of different media; the eyes, peculiarities, use, and protection; mounting, dry, in liquid, and in cells; section cutting, soft and hard tissues, crystals, rock sections and grains; staining; high-power objectives, use and care, cover connections, and immersion fluids; adulteration of foods, drugs, etc., detection of fibers, paper, and handwriting.

Microbiology.—Laboratory examination of unicellular forms of life, yeasts, protozoa, ameba, the molds, algae, and fungi of fresh waters; fauna of potable waters.

General Bacteriology.—Isolation, preparation of culture media, mounting and study and identification of species, bacteria of potable waters, sewage bacteria, typhoid bacillus, biological examination of Croton water, Brooklyn aqueduct water, etc., bacteria of the atmosphere, biological analysis of air of hospital wards, class rooms, etc., disinfectants and filters, bacteriological tests.

VI.—Application, whenever necessary, will be made to the Commandant of the Naval Station, New York, for authority for the medical officer assigned to the duty, in company with the assistant surgeons undergoing instruction, to visit receiving ship, and all modern ships in commission, ships undergoing construction and nearing completion, that may be at the navy yard, for the purpose of inspection of every part of the vessel, and gaining information relating to general arrangement of sick and other quarters, system of ventilation and heating, air space, etc.

VII.—When assistant surgeons are assigned for instruction in specified branches to hospital, examining board, or laboratory, the senior officers thereof shall appoint, as they may deem advisable, the medical officers under them as instructors in the special work, assigning to each such subjects as may be agreed upon by consultation, care being taken that the system of instruction will necessitate everything in writing. The student must carefully prepare all reports on the subjects assigned to him before presenting them to the instructor for inspection and remarks. When papers are completed they shall be delivered by the instructor to the senior officer of the hospital, examining board, or laboratory, as the case may be, who will retain them until all papers prepared by the student during his term of instruction are received, when they shall be forwarded to Director of Naval Laboratory and Department of Instruction, in accordance with prescribed form.

VIII.—Medical officers, when assigned as instructors, whether attached to laboratory, hospital, or examining board, shall keep an accurate record in book form of all work required of assistant surgeons undergoing instruction. These record books, when completed, shall be delivered to the Director of the Naval Laboratory and Department of Instruction to be placed on file. They will also see that assistant surgeons are provided with everything necessary to prosecute their work in an intelligent manner; use of apparatus for qualitative, quantitative, and organic analysis, for microscopy, and for bacteriology and chemical reagents for practical work in laboratory or elsewhere, use of surgical instruments and appliances for hospital work, free access to library, and use of modern text-books on every subject taught.

IX.—Assistant surgeons will be held responsible for the proper care and safe return of instruments, books, microscopes, apparatus of all kinds, etc., placed in their charge during course of instruction.

X.—When the professional record of an assistant surgeon is completed, and all papers prepared by him on subjects assigned at hospital, examining board, and laboratory have been received by the Director in charge of the Laboratory and Department of Instruction, he shall see that they are properly compiled and transmitted to the Bureau of Medicine and Surgery, in accordance with the prescribed form.

XI.—The assistant surgeon's professional record will be kept on file in the Bureau of Medicine and Surgery until he becomes eligible for examination for promotion, when it will be transmitted to the Naval Medical Examining Board for inspection, to be returned to the bureau on completion of his examination. This record, together with examination papers of both first and second examination, will then be bound in book form and kept for future reference, as a guide in assignment to duty, according to professional and other qualifications.

Borax in the Treatment of Epilepsy.—In an article published in the July number of the *Liverpool Medico-chirurgical Journal*, Dr. William Alexander says:

"The medicinal treatment of epilepsy is a wide subject, and can not be dealt with at the end of a paper like this; we will only deal with one or two phases of it.

"At the present time it resolves itself into the administration of bromide of potassium, varied by the occasional addition or substitution

of bromides of sodium, ammonium, or strontium. We have in bromides a powerful means of controlling this disease, but the question of cure by their aid is entirely unsettled and exceedingly doubtful. In ninety nine cases out of a hundred a medical man called to a case of epilepsy will prescribe bromide of potassium, and the prescriptions of specialists who have been consulted by an epileptic all contain bromides. In our experience, we have no hesitation in saying that this universal treatment by bromides is often disastrous.

"Here is the substance of a letter from a very intelligent mother, who reported to us her experience of the treatment of her son, and which illustrates the present practice from a lay point of view:

"She says: 'At about the age of nine years our son developed occasional slight spells of *petit mal*. We consulted Dr. —, who pronounced him epileptic. He had not then had any actual fits. Bromide of sodium, ten grains three times a day, prescribed. His first seizure occurred when he was ten years and a few months old. Seizures at first came at intervals of months, then weeks, one at a time.

"At twelve years old saw Dr. —, who prescribed bromide of ammonia, with no good result. Has seen many doctors, including Dr. — again, who all range the changes on bromides of various kinds with monotonous persistency, until the poor boy became a physical and mental wreck. His tongue seemed paralyzed, he could with difficulty articulate, and sat in a dazed condition, taking interest in nothing. During his fits, even during the attacks of *petit mal*, he was unable to retain his urine. He was a pitiable sight, and had become reduced to this condition by bromide, as I shall prove.

"In February last, when taking about sixty or seventy grains of bromide of soda each day, as he had been doing for years, he had thirty-four fits—ten one night, four another, and so on. In despair, I left off giving him the useless stuff. Some one casually spoke to me of borax as an alleviator, and on the 5th of March I began giving him twenty grains powdered borax three times a day. In March he had eighteen fits, in April two. In May I had reduced the dose and he had five. In June, having resumed the full dose, none at all. In July, on the 30th, one slight fit, nine weeks having elapsed since the last. In August none, but he began developing a kind of eczema. I gave up the borax on that account on the 11th of September; and although I have resumed giving it again, it seems somehow to have to some extent lost its virtue. In September he had four fits, and so far in October eight. His fits at present occur on awakening in the morning, and are preceded by a prolonged attack of *petit mal*, with occasional cries and jerks. However, although the borax is failing a little in its effects, he is like a different person—bright, active, and energetic. He reads, writes, plays on the piano, and takes an interest in all that goes on. His mind has been checked and is undeveloped, like a child's mind, and am afraid the bromide has mentally maimed him for life.'

"This letter describes in a mother's eloquent language our impression of the perniciousness of the treatment of chronic and confirmed epilepsy by large and increasing or constantly repeated doses of bromides. We would go further, and deny that bromides, thus given, produce an arrest of the attacks, of sufficient extent, and in a large enough number of cases, to counteract their baleful effects on the brains of many patients.

"We have now met with many patients where the fits have been arrested, and in a considerable number permanently arrested so far, under various methods of treatment; but we do not remember any cases where large doses of bromide constituted the treatment. We may arrest the fits by bromides, as we have already said, for a time, but it is generally at the expense of the patient's brain: a few take the drug kindly, and the benefit seems unmingled, but these cases are very few.

"We could detain this meeting all night with cases culled from our experience at Maghull, where patients have come there after years of treatment with bromides—one, two, or even more drachms a day—misérable, pustule-marked, introspectively inclined creatures (that is, if they have got any acting, unbrunized brains left), with feelings and fads and nervous symptoms, minds and bodies blighted or apparently wrecked.

"A few months of rational treatment will probably not make much difference in the number of attacks, which burst out again as soon as

the bromide is stopped, but the patients soon appear like different beings, can think rationally, and of something else but themselves, and it becomes a pleasure instead of a pain to converse with them, and to study their welfare.

"Attacks of epilepsy temporarily stupefy the patient and upset the mental faculties, but this effect is quite different and generally of a less serious nature than the deterioration produced by bromide. For these reasons, we rarely give greater doses of bromide than five grains, three times a day. Larger doses are very rarely required except as a sort of medicinal police, and, like the police, are only required when a case becomes refractory, to be dispensed with when the patient becomes amenable to ordinary treatment.

"In the letter from the lady referred to above, reference was made to the use of borax in the treatment of epilepsy. We have used it pretty extensively for several years, as it seems a comparatively harmless drug, and we will conclude this paper with a description of the results of our employment of it.

"Borax alone has much disappointed us, although we know of several cases in which it has acted as a charm; but we are inclined to believe that it acts best when given after the use of bromide, or especially in conjunction with small doses of bromide.

"Statistics of the results of the treatment of epilepsy are never final except they cover many years, and when the comparison of the effect of using different drugs is made under conditions that are somewhat similar. It is very hard to obtain conditions that are similar, but at Maghull we have the best approximation to similar conditions that has hitherto been obtained in this country.

"We need not trouble you with a table showing the effect of giving borax alone at Maghull, because it failed in all the cases in producing any decided benefit.

"Mixed with small doses of bromide of potassium it had a better effect, but with bromide of sodium the result seemed to be still better, and for some time we have used the following prescription in a considerable number of cases:

"B Sodii biborat.	gr. 200;
"Sodii bromid.	gr. 50;
"Syr. simplic.	℥ j;
"Aq.	ad ℥ x.
"℥ j t. d. ex aq. p. cib.	

"Sometimes, but rarely, a fourth dose is given. The following statistics have been prepared by me of the effects of this prescription on patients who have been treated with it for a sufficient time to allow of an impression being made.

"The previous treatment was very varied, and it would be too tedious to present it all before you. It included all kinds of bromide treatment, regular and irregular; also indifferent treatment, where the general health only was attended to; and finally, cases where other reported specifics, such as zinc, antipyrine, simulo, etc., were given.

"Although this method of treatment has a good influence on the attacks, its beneficial effect on the mental condition of the patients is much more uniform. A great many of the patients showed symptoms of post-epileptic or periodical mental disturbance. Several of them were stupid and dull for several days, and a few were bedridden and helpless at times, and required then to be treated as imbeciles. These mental disturbances have almost disappeared, and the patients have been saved the necessity of confinement in lunatic asylums. In fact, in several instances the secretary had warned the friends that removal from the Home would probably be necessary on account of the mental disturbances frequently evinced after admission. Owing to the great improvement in their mental state under treatment, we have never required the notice to be carried out.

"If my report of this method of treatment had not some drawbacks, it might be considered too favorable. Fortunately for our credit, there are some objections to it, but these are entirely physical.

"1. The full dose sometimes produces gastric troubles, flatulence, indigestion, gastrodynia, and loss of appetite. The drugs may be either lessened in quantity or stopped for a time, and the medicine should always be given after meals, and well diluted. After a little caution

in gradually increasing the dose, combined with careful dieting, the patients become inured to the medicine, and can take it without any effort or apparent immediate after-consequences.

"2. An erythema of the skin, that in some cases approaches an eczema, is frequently observed after the medicines have been taken for a time: this is sometimes very severe, and productive of much itching and irritation; in some cases it is intolerable, and the drugs may have to be stopped for a time, when it immediately subsides. In most cases we encourage the patient to persevere with the medicine, knowing that the skin disease gradually subsides, and that the cases that persevere are those most benefited, as a general rule. In this there are, however, some marked exceptions.

"Daily immersion in alkaline baths relieves the symptoms very much, and the inunction with vaseline or other simple lubricant is most useful when the medicine is left off for a short time until the eczema subsides: its resumption is not generally followed by the reappearance of the skin disease, or if it does appear, its severity is much reduced.

"3. Loss of hair is a more striking, more unexpected, and fortunately much rarer phenomenon."

The Training of Nurses in the Methodist Episcopal Hospital, Brooklyn.—The following appears in the *Fifth Annual Report* for 1892:

"This course extends over a period of two years, and includes the outlines of anatomy and physiology, hygiene, general and special medical nursing, general and special surgical nursing, and more particularly of: 1. The dressing of blisters, burns, sores, and wounds; the application of fomentations, poultices, cups, and leeches. 2. The administration of enemata and use of catheter. 3. The management of appliances for uterine complaints. 4. The best method of friction to the body and extremities. 5. The management of helpless patients; making beds; moving, changing, giving baths in bed, and preventing and dressing bedsores. 6. Bandaging, making bandages and rollers, lining of splints. 7. The preparing, cooking, and serving of delicacies for the sick.

"Instruction is also given in the best practical methods of warming and ventilating sick-rooms in a proper manner. Pupils are taught to take care of rooms and wards; to keep all utensils perfectly clean and disinfected; to make accurate observations and reports to the physician of the state of the secretions, excretions, pulse, skin, appetite, temperature of the body, intelligence—as delirium or stupor—breathing, sleep, condition of wounds, eruptions, formation of pus, effect of diet, or of stimulants, or of medicines, and to learn the management of convalescents.

"The instruction is given by the attending physicians and surgeons, the senior interne of the hospital, and the supervisor of nurses.

"The teaching includes frequent stated lectures, recitations and demonstrations in the class room and at the bedside of the patients. All the nursing of the hospital is done by the pupils under the direction of the supervisor of nurses. Examinations are made at stated periods to test the proficiency of the pupils.

"Those wishing to obtain this course of instruction must themselves apply to the supervisor of nurses at the hospital, Sixth Street and Seventh Avenue, Brooklyn, N. Y., either in person or by letter, upon whose approval they will be received for two months on probation. The preferable age for candidates is from twenty-five to thirty-five years. The applicant should send, with answers to the paper of questions, a letter from a clergyman testifying for her good moral character and from a physician stating that she is in sound health. Applicants are received at any time during the year when there is a vacancy, except in July and August. During the months of trial and previous to permanent acceptance as a pupil nurse, the applicant must be prepared for an examination in reading, penmanship, simple arithmetic, and English dictation. The examination is to test the applicant's ability to read aloud well, to write legibly and accurately, to keep simple accounts, and to take notes of lectures. This amount of education is indispensable, but the applicants are reminded that women of superior education and cultivation, when qualified as nurses, will be preferred to those who do not possess these advantages.

"During the months of probation the pupils are boarded and lodged at the expense of the hospital, but receive no other compensation. They are not expected to wear the uniform of the hospital, but must come prepared with dresses of washable material for use in the hospital. All clothing must be plainly marked. Those who prove satisfactory will be accepted as pupil nurses after signing the following agreement:

"I, the undersigned, hereby agree to remain two years in the Methodist Episcopal Hospital as a pupil nurse, and to obey the rules of the institution."

"At the end of the first six months the record and work of each pupil are again carefully scrutinized as to her fitness for the vocation of nursing, and the right is reserved by the authorities of the hospital to terminate then the connection of the pupil with the school if it should seem to them best.

"The connection of any pupil with the school may be terminated at any time by the superintendent of the hospital for inefficiency, misconduct, or a generally unsatisfactory record.

"The pupils will reside in the Nurses' Home, and serve for the first year as assistants; the second year they will be expected to perform any duty assigned to them by the supervisor, either to act as nurses in the hospital or to be sent to private cases among the rich or poor. Board, lodging, and washing will be furnished without charge.

"An allowance of \$8 a month is paid during the first and \$12 during the second year. The sum is intended for the dress, text-books, and other expenses of the nurse in connection with her work, and in nowise as wages, it being considered that the education given is a full equivalent for their services. They are required, after the months of probation, when on duty, to wear the dress prescribed by the institution—white cap and apron and linen collar. The day nurses are on duty from 7 A. M. to 7 P. M., with the exception of time for exercise or rest. They are also frequently given an afternoon, and have a right to a part of Sunday. A vacation of two weeks is allowed each year.

"When the full term of two years is ended, the nurses thus trained can choose their own field of labor. On leaving the hospital they will, after passing a final examination, each receive a diploma signed by the president and secretary of the board of managers, and president and secretary of the medical board.

"To secure success in prosecuting this course of training for the vocation of a nurse, there is needed, in addition to a healthy body, an alert mind and a fair education, a capacity for punctuality, strict obedience to orders, and exact statement. But these military virtues must be wisely tempered with womanly pity and tenderness; not, however, degenerating into a good-nature which will work harm to her patient. A vast ability for painstaking and careful attention to details should form part of her equipment. As a necessary consequence, she should possess an exalted enthusiasm for her work and a broad conception of her honorable mission, in order to overlook the thousand and one unpleasant and trying features of her daily life.

"Her personality—mental, moral, and physical—should be bright, pure, and wholesome. Personal comfort should be sacrificed and selfishness obliterated while the nurse is fulfilling her duties. 'The gentler born the maiden, the more bound to be sweet and serviceable.' Great tact and discretion must be her inheritance. The secrets of her patients she must guard as do the clergyman, lawyer, and physician. Coolness and self-possession in emergencies are necessary. A desire to study, to learn, a healthy unrest, should distinguish her mental attitude. In short, allowing for the natural imperfections of human nature, the trained nurse should have an ideal, which she must patiently strive to emulate—a perfect woman nobly planned; plus the advantages of special education and culture. Nor must she be discouraged, for training, self-discipline, and practice will do wonders toward the attainment of the goal.

"Those wishing to engage in the more earnest work of life, with a taste for this essentially woman's work, can find no better field for their energies than this of nursing the sick. It should not be lightly undertaken, however, as without the spirit of consecration there is often much that is distasteful and wearisome in the work that has to be done."

Contravention of the Oath of Hippocrates.—In that memorable oath which the Father of Medicine made binding on all who entered on the study and practice of the healing art there is no passage more honorable in its conception or more solemn in its language than that which relates to the confidence between the patient and his medical attendant. Civilization in its most elevated and refined developments has not improved upon it—therein affording another confirmation of what in the *Novum Organum* Bacon observes of physical and moral science, that whereas the former is susceptible of infinite advance so that no limit can be put to its many-sided evolution, the latter attained its maturity early, inasmuch that in nearly all essentials it may be regarded as stationary. The passage in question runs as follows: "If in treating a patient, or even independently of treating him, I shall have seen or heard anything as to his life which ought never to be spoken of in public, on this I shall preserve silence, deeming particulars of this nature as not proper to be revealed" (*ἀρρήτα ἡγούμενος εἶναι τὰ τοιαῦτα*). To the honor of the profession be it recorded that the instances are rare indeed where this obligation to secrecy has been violated—an honor none the less notable that in the words of a profound student of human nature "a man, in order to save his life, will tell a physician or surgeon what he would not disclose to a lawyer to save his fortune, or to a clergyman to save his soul." Rare, therefore, as are the violations of this reticence on the medical practitioner's part, it is not to be wondered at that the penalties attaching to them are so severe or that the retribution with which a deplorably indiscreet physician has just been visited abroad receives such publicity in the European press. Two months' imprisonment and the withdrawal of his medical diploma for five years are announced as having been meted out to him for his having "trahi le secret médical, c'est à-dire, raconté à des tiers les maladies dont quelques-uns de ses clients étaient atteints." Besides this professionally disqualifying punishment he has been sued in the civil court by several of the patients whose confidence he had abused and has been condemned to pay damages amounting in some cases to two thousand marks, in others to four hundred, according to the gravity of the offense. To live down such a blot on professional fair fame can be no light undertaking. Indeed, as a contemporary puts it, "il ne lui reste plus qu'à s'expatrier, car il ne retrouverait pas un malade à soigner dans son pays." So accurately, it appears, did the Father of Medicine anticipate the moral standards of the nineteenth century, so sagaciously has he formulated a code of professional honor which humanity, after more than two millenniums of experience, can but interpret and apply.—*Lancet*.

The late Dr. John William Branham.—The surgeon general of the Marine-Hospital Service has issued the following circular, dated August 28, 1893:

"To the Medical Officers and Acting Assistant Surgeons of the United States Marine-Hospital Service:

"It becomes my painful duty to announce the death from yellow fever of Assistant Surgeon John W. Branham, at Brunswick, Georgia. He was taken ill about August 10th while in the performance of quarantine duty at Brunswick, and died on the afternoon of the 20th.

"Assistant Surgeon Branham was born in Walker County, Georgia, October 27, 1868, and his early education was derived from the schools of his native State. When he was thirteen years of age he moved to Baltimore, Md., and received a general education at the Baltimore City College. He then studied medicine at the College of Physicians and Surgeons, Baltimore, and graduated at the head of his class from that institution March 13, 1889. During this time his elder brother, Dr. J. H. Branham, of Baltimore, was his preceptor. After graduation he first served as resident physician at the City Hospital in Baltimore during part of 1889 and 1890, and afterward was assistant quarantine physician for the port of Baltimore from May until November, 1891. Leaving Baltimore, he moved to Kempsville, Va., where he practiced medicine until entering the medical corps of the Marine-Hospital Service. At the examination of candidates, held in Washington, D. C., in March, 1893, Dr. Branham passed first among twenty-two applicants, and was commissioned assistant surgeon April 19, 1893, and on April 21st was ordered to the Marine Hospital, Stapleton, Staten Island. On the 25th of July Assistant Surgeon Branham was ordered to Brun-

wick, Ga., to take charge of the quarantine at that port, where he remained in the active discharge of that duty until he was stricken down with yellow fever.

"As an officer, Assistant Surgeon Branham was held in high esteem both by those under whom he served and by the department. His ability was fully recognized, and he was chosen for the important duty of reorganizing the quarantine of Brunswick and establishing it upon a firm sanitary basis, the local quarantine at that point having proved to be insufficient. Through his death the service has lost an able officer.

"Personally, Assistant Surgeon Branham was a man whose general education and medical attainments won for him the highest respect, and his social relations with his brother officers and others were characterized by a manliness of deportment and gentlemanly bearing that won the affection of all.

"I have extended to his family the sympathies of the corps."

To Contributors and Correspondents.—The attention of all who purpose favoring us with communications is respectfully called to the following:

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Contributors who wish to order REPRINTS of their articles should do so on a blank prepared for that purpose, which will be sent to them by the publishers on receipt of a request to that effect. The order should be sent to the publishers, and not to the editor.

Original Communications.

STUDIES IN INFANT FEEDING.*

By HENRY DWIGHT CHAPIN, M. A., M. D.,

PROFESSOR OF DISEASES OF CHILDREN
AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THERE are certain requisites for an infant's food before it can be recommended for general use. Thus, it must be readily procurable under the common and ordinary conditions of life; it must be digestible, nourishing, and fairly cheap. The mixing or preparation of such a food must not be too complicated. The conditions here mentioned can only be met by employing cow's milk, more or less diluted or altered, according to the necessities of the case. The following paper contains no new principles, but is rather a record of experience in the simplest manipulation of cow's milk to make it most acceptable to the infant's stomach and digestion. The clinical experience has been principally derived from the babies' wards of the New York Post-graduate Hospital, where the infants are subjected to close scrutiny and constant weighings during periods varying from several days to as many weeks, and sometimes even longer. Those who have had a large dispensary and hospital experience in artificial infant feeding among the poor can not have failed to notice the frequent tendency to atrophy. This is often so extreme as to cause death. Even in cases not so marked there is almost universally present a condition of underweight. Many unfavorable hygienic conditions favor this deplorable result, but the principal cause is the nature and quality of the food that is administered. This grave tendency toward atrophy should constantly be borne in mind in all studies bearing on artificial infant feeding.

The milk as ordinarily delivered on a given morning in New York, and doubtless in other large cities, consists of a mixture resulting from the milkings of the previous morning and the night preceding, thus being from twenty-four to thirty-six hours old. If the milk dealer knows his farmers, he can sometimes induce them to put the twenty-four hours' milk in a can by itself, which is a gain as regards infant feeding. What is urgently needed is more scrupulous cleanliness in the handling of the cows and milk upon the farm, and quicker and more frequent methods of transportation of the milk to town in order to represent a real gain in the feeding of infants. It need hardly be mentioned that the average milk from a herd of cows is better and safer than the traditional one cow's milk. As soon as the milk is received in the early morning it is put in a tin pail or wide-mouthed vessel that is covered and allowed to stand in a cool place for three hours. The top half only of this milk is to be administered to the infant, as advised by Dr. Meigs. This top portion is best separated by being carefully dipped off by a cup or ladle. If decanted, both layers of the milk will become mixed by the lower part

rising when the vessel is tipped. At the babies' wards a long glass cylinder is employed, which is graduated and furnished with a stopcock at the bottom. After standing the required time, a distinct difference is noted in the two portions of the milk, which are easily separated by drawing off the lower half and reserving the remainder for the infant's use. In order to learn exactly what difference the simple process of standing would make, the two parts of the milk were analyzed with the following results: One gallon was drawn from the bottom of the cylinder, well mixed, and a sample taken which showed:

Fat (1)	3.0	per cent.	Total solids (1)	12.29	per cent.
(2)	3.0	" "	(2)	12.44	" "
(3)	3.1	" "	Mean	12.36	" "
Mean	3.03	" "		3.03	

Solids not fat 9.33 " "

The upper portion of the milk, one gallon, was well mixed and a sample showed:

Fat (1)	4.9	per cent.	Total solids (1)	14.01	per cent.
(2)	4.8	" "	(2)	14.02	" "
(3)	5.0	" "	Mean	14.015	" "
Mean	4.9	" "		4.9	" "

Solids not fat 9.115 " "

This analysis shows that practically the only change on standing is a rise of fat. This, of course, slightly raises the percentage of other solids in the lower portion, since the abstraction of any constituent from a mixture raises the percentage of all the remaining constituents. The upper portion contains, roughly, five parts of fat for every three parts contained in the lower portion. The minimum of fat allowed for genuine milk is three per cent. The increased amount of fat thus procured, in the part of the milk to be used, represents a real gain in feeding the infant. The newer analyses of milk do not confirm the older view that cow's milk contains more fat than human milk, but rather the reverse. Thus Professor Leeds found, upon analyses of forty-three samples of woman's milk, an average of 4.013 per cent. of fat, while upon analyses of eleven samples of whole market milk the average percentage of fat was only 3.75 per cent. König finds the average of fat in woman's milk to be 3.90 per cent., and in cow's milk 3.66 per cent. Professor Rotch places the average of fat in both cow's and woman's milk at four per cent. As cow's milk has to be more or less diluted before being administered to the infant, the necessity of starting with a preparation that is rich in fat will be apparent. The next step to be taken is to see that all fermentation in the milk is stopped. Cow's milk, as ordinarily procured, must be treated for its biological as well as its chemical properties. The well-known process of sterilization aims to fulfill this object. Partial sterilization, or pasteurization, to the point of killing the germs only, is necessary and desirable. The high and continuous temperature required to destroy spores produces various unfavorable changes in the milk. Practically, all that is required is to submit the milk to sufficient heat to destroy the bacillus of lactic-acid fermenta-

* Read before the Section in Pædiatrics of the First Pan-American Medical Congress.

tion which causes the souring of milk. This bacillus has been described as of small oval form, occurring singly and in pairs. It is easy, by prolonged and repeated applications of high temperature, to keep milk indefinitely from souring. By reheating once or twice, it can be kept for months without any sign of acid fermentation. Such milk, however, is by no means fit for administration to the infant, as the fat collects in masses and changes have taken place in the albuminoids. The casein is altered, the milk remaining more or less liquid in the stomach, as the action of the stomach acids and of the lactic ferment on the casein of sterilized milk is incomplete. Analyses of excrement show more nitrogen and more fatty acids after feeding with sterilized milk than with raw milk. Not only is the digestibility of the milk diminished by long heating, but the necessity for it indicates so many bacteria that their excreta, which can not be rendered harmless by heat, may cause poisoning. It has been found that milk well sterilized will, after a certain interval of time, undergo a species of decomposition with an alkaline reaction. Dr. Koplik states that the alkaline fermentation has not been investigated to such an extent that we can with certainty pass upon the deleterious or non-deleterious effects upon infants of the products of this decomposition. It is enough to know that it takes place, and certain alkaloidal elements are very slowly but surely produced. Accordingly, this writer condemns the storage of sterilized milk and its subsequent use after prolonged periods, and I concur in this opinion. Simply sufficient heat must be applied to the milk to keep it sweet until the next supply can be procured. An ordinary double boiler, such as is found in every kitchen, will meet all the requirements of average heating. The Arnold steam cooker may prove more convenient, and Freeman's pasteurizer is handy and efficient. As a rule, fifteen minutes' heating is sufficient with the bottles well plugged with cotton. The addition of a one-per-cent. solution of peroxide of hydrogen is a safe preservative of milk for some hours, when heating is undesirable or not convenient. If more scrupulous care were exercised at the source of the milk supply, and the impurities completely separated by the centrifugal process, in the great majority of cases no means at all for preservation need be employed, and an advance in this direction is urgently needed.

We still have facing us the old and difficult problem of how to act best upon the tough, leathery curds of cow's milk as to make them most acceptable to an infant's weak digestion. Not only are the albuminoids much greater in amount in cow's milk, but the portion coagulable by acids is greater than the non-coagulable part, while in woman's milk the non-coagulable part much exceeds the coagulable portion. Hence the dilution of cow's milk, while reducing the albuminoids to a proper percentage, does not necessarily render the clot sufficiently soft to be readily digested by the infant. The question whether the size of the curd stands in any relation to the substance used as the diluent has been disputed. It has been taught that by adding gruels of the cereal grains to the milk the clot is mechanically attenuated. Dr. Rotch states, on the contrary, that practically the size of the curd depends simply on the dilu-

tion of the albuminoids and not upon the particular menstruum used.

Clinical results, however, point plainly to the utility of diluting with barley water, except in very young infants, and I believe the beneficial effects are, to a certain extent, due to a lessening of the compact character of the clot. In order to test this, the following experiment was made by Dr. Eiloart: Equal parts of milk and barley water were taken, and grm. 0.1 of hydrochloric acid was added to 100 c. c. of the mixture. This strength was employed, as in gastric juice there is grm. 0.2 of hydrochloric acid to 100 c. c. of fluid, which, on dilution by the contents of the stomach, is weakened somewhat, so that grm. 0.1 is a fair estimate for the experiment. Some albumins require 0.2 per cent. hydrochloric acid added to pepsin in artificial digestion to obtain the best results, but casein and vegetable albumin are digested best by 0.1 per cent. of hydrochloric acid.* This experiment showed the casein formed in finely divided clots. Next, equal parts of plain water and cow's milk were taken and grm. 0.1 hydrochloric acid added to 100 c. c. of the mixture. This showed larger clots than before. A number of repetitions gave similar results, using various coagulating agents when plain water and thin gruels were used as comparative diluents. When rennet alone was used as the coagulating agent, the results were so different from those obtained when hydrochloric acid was used with the rennet that recourse was had to the stomach itself, with results given in the accompanying paper by Dr. Eiloart. The disadvantage in the employment of wheat or barley flour consists in the large proportion of starch contained in these grains, which may be great in very young infants. This starch may be rendered more soluble and easy of assimilation by heat or diastatic action. In many cases the effect of prolonged heating upon barley and wheat flour seems to have a beneficial effect, particularly when there is a tendency to diarrhoea. The good results of the old flour ball, made by prolonged boiling of the wheat flour in a bag, have long been recognized. But the heat so applied does not produce its beneficial effect by chemically changing the starch, but probably from some physical alteration which renders it more effective as a diluent.

The effect of dry heat upon starch is to produce changes into soluble starch, retrodextrin, achroodextrin, and finally a small percentage of dextrose and maltodextrin.† The higher dextrins are more soluble. Starch does not begin to dextrinate until 250° F. is reached, and this temperature should be maintained for several days if there is any quantity to be changed. At between 350° F. and 400° F. dextrination may take place in a few hours. It is evident that such a high temperature can not be maintained by any domestic process. If put into an oven the flour will soon be scorched or burned. An interesting experiment was made by Dr. Eiloart upon barley flour that had been heated for a week in an ordinary double boiler. The water in the under vessel was allowed to boil for a week, with the ex-

* Hammarsten. *Lehrbuch der physiologischen Chemie*, 1891.

† Stohmann and Kerl. *Muspratt's Chemie*, Bd. xi, Braunschweig, 1889.

ception of a few hours at night, the dry flour in the upper vessel being thus exposed to as high a constant temperature as possible under the circumstances. An analysis of the unheated meal taken from the same barrel yielded two thirds more sugar and one quarter more dextrin than the heated meal. The cause of this is that the diastase, whose function it is to convert starch into sugar and dextrin, is partially paralyzed by heat, the ferment undergoing this change at about 175° F. This method of acting upon the starch was accordingly abandoned, and the necessary change effected easily and quickly by means of diastase. Starch treated with diastase is split up quickly into maltose and dextrin, and the longer the action is continued, the higher dextrin will be formed, such as achroodextrin and maltodextrin. After a number of experiments and analyses, Dr. Eiloart devised a receipt for which I am indebted to him, and which has been used at the babies' wards, consisting of a mixture of barley or wheat flour treated with diastase,* the temperature of digestion being regulated by the addition of hot and cold water in proper proportion. The complete description of the process will be found in Dr. Eiloart's paper.

This food can be easily and cheaply prepared in any household, and while the starch is changed to more soluble forms, there is not an excess of sugar. Herein it is superior to the various Liebig's foods. The nutritive value of the albuminoids is likewise not lost sight of.

Either barley, wheat, or oatmeal may be thus treated, the principal difference being the varying proportions of fat contained in these grains. According to Dietrich and König, the percentage of fat is as follows: Barley, 2.09; wheat, 1.55, and oats, 6.09. This may be borne in mind in prescribing for diarrhœas and the various forms of indigestion.

The effect of malt upon milk is to favor its digestion and assimilation. Garup Besanez, a German authority on malt, has found a ferment in the germinated seed of vetches, hemp, flax, and barley, which very energetically converts starches into grape sugar, and albuminous substances (fibrin) into peptones. It was afterward found that diastase has no action upon albuminoids, but peptase—which is generated in germinating grain at the same time and under the same conditions as diastase, and practically they can not be separated—acts upon proteids slowly at low temperatures. This substance is an analogue of the vegetable proteolytic ferments found in pineapple juice and the papaw plant.

The actual results obtained from the use of food thus prepared in the babies' wards have been good, considering the class of cases treated. During May, June, and early July thirty-seven infants suffering from various degrees of gastro-intestinal irritation and inflammation, and from one to ten months old, were thus fed. Seventeen increased slightly in weight after a week or so, sixteen lost a little in weight, and four remained stationary. As is well known, the loss of weight in gastro-intestinal affections during infancy is usually well marked, and is exceptionally rapid in hospital

and institution infants. So extremely susceptible are young infants to hospitalism that they invariably lose weight after a certain interval of time, and will die of inanition under any system of artificial feeding unless removed in season. A baby admitted May 26th, one month old, having had convulsions from gastro-intestinal irritation, exemplifies this fact. The weighings are registered as follows: On admission, six pounds one ounce; May 30th, six pounds four ounces; June 2d, six pounds six ounces; June 6th, six pounds eight ounces; June 9th, six pounds five ounces; June 13th, six pounds two ounces; June 16th, five pounds and ten ounces; discharged. The gastro-intestinal irritation subsided and the baby did well on its food, but at the end of two weeks it began to show the effects of hospitalism, although there was no vomiting or other sign of indigestion. When sterilized milk, diluted to the proper point with water, limewater, or plain barley water, has been used, there is almost invariably a steady and slow loss of weight from the first, so that the change so often noted upon malting the preparation can not fail to be gratifying. Dr. Judson C. Smith, who is the district visitor for the hospital, seeing a certain number of the patients after they have been discharged, tells me he has used the extract of malt to peptonize milk about a year, both for infants and adults, with very satisfactory results. Babies from four months to one year old, when losing weight on other methods of feeding, have usually gained flesh and improved in every way on milk prepared with malt. One tablespoonful of malt is added to a pint of milk, which is heated from twenty to thirty minutes and then brought to the boiling point. The milk is then diluted with water according to the age of the infant.

A FOOD FOR INFANTS, WITH EXPERIMENTS, CHEMICAL AND PHYSIOLOGICAL.*

By ARNOLD EILOART, Ph.D.,
DIRECTOR OF THE CHEMICAL LABORATORY,
NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE experiments here described were intended to throw light upon two problems. The first was the formation from cow's milk of a curd resembling in fineness that from woman's milk. The importance of this seems evident,† and Uffelman‡ has shown that in artificial digestion the proportion of peptone formed is greatest when the curd is loosest. He recommends mixing cow's milk with three fourths its volume of 0.2 per cent. hydrochloric acid in order to make the casein like that of human milk.

Munk,§ having tried Scherff's process of sterilization (heating to 100° C. under a pressure of three atmospheres), states that milk so treated clots *in the stomach itself* in

* Maltine was the preparation here yielding the diastase.

* Read before the Section in Pædiatrics of the First Pan-American Medical Congress.

† Ellenberger and Hofmeister, however, object to the fine curd of sterilized milk, because it may pass too quickly through the system and thus escape complete digestion (*Molkerei Zeitung*, 1892, 6).

‡ Pfüger's *Archiv*, 29, 399.

§ *Deutsche med. Woch.*, 1881, No. 36.

flocks like woman's milk, not in compact masses like ordinary cow's milk.

It seems unlikely, however, that these methods will come into general use, and the following work has been confined to testing diluents which are everywhere available.

The result of a preliminary investigation was surprising, for it appeared that the fineness of the curd depended more on the curdling agent than on the diluent mixed with the milk. Thus, with rennet, mixture A curdled finer than mixture B, while with hydrochloric acid, one per cent., mixture B curdled finer than mixture A.*

Hence the test-tube experiments, which have constantly been quoted to show the effect of various diluents, must be abandoned, and the infant's stomach itself must be consulted to decide what mixture will curdle finest in that stomach. Accordingly, the mixtures to be tested were administered to infants, and after a short interval withdrawn by means of the stomach pump. I am indebted to Dr. Chapin for the opportunity of carrying out these tests in the babies' wards of this hospital.

In the following table I have used figures to indicate degrees of fineness of clot, calling the finest curd 1:

TABLE I.—*Showing Fineness of Clot and Acidity of Stomach Contents after feeding with Milk and Various Diluents. Fresh Milk was used except where Sterilized is mentioned.*

Throughout this work the regularly prescribed malt preparations were used as the source of the diastase; + means a small dose, ++ a full dose.

The figure 4, indicating the very coarse clot sometimes obtained with hydrochloric acid (0·1 per cent.), is absent from the record of stomach clots, although the percentage

* Mixture A was equal parts of milk and water; mixture B was equal parts of milk and barley water. With a mixture of hydrochloric acid and rennet the result was the same as with the acid alone. In every case the volume curdled was 100 c. c.; very small quantities fail to show the differences in the curd.

of acid in the stomach, calculated as hydrochloric, sometimes rises almost to 0·1 per cent.

The chief conclusion to be drawn from the stomach experiments is that the coarseness of curd increases with the percentage of acid. Thus the finest curd (called 1), which was only once obtained, occurred when the acidity was 0·0467 per cent.; the curd next in fineness occurred in six cases in which the mean acidity was 0·062 per cent.; whereas for curd 3 (rather coarse) the acidity averaged 0·072 per cent. (mean of nine cases).

So far we have left out of account the diluent used. If we arrange the results so as to show the number of times a given diluent produced a curd of the second or third degree of fineness, we find that water gave clot 2 once, clot 3 four times; barley water gave clot 2 three times; diastase, with or without cereals, gave clot 2 twice, clot 3 four times.

So far the results proclaim barley water to produce the finest and water the coarsest curd. But when we take into account the acidity in the different cases, we find it to average in the three barley-water experiments only 0·053 per cent., while in the four water experiments it is 0·077, and in the case of the diastase preparations, which yielded curds

almost as coarse as the water mixtures, the acidity is nearly as high—viz., 0·071 (average of the six cases).

The good results apparently due to the barley water may, therefore, be due in reality to a low percentage of acid. On the other hand, further experiments may show that barley water itself causes the low percentage of acid.

The influence of the concentration of the curdling agent is well seen in the following experiment, made with

an adult: A mixture of 500 c. c. milk with 500 c. c. water at blood-heat was taken. Two minutes afterward 360 c. c. were pumped out from the stomach; six minutes later 400 c. c. more were removed; eight minutes later the rest was removed.

The first portion was curdled so fine that close examination was needed to see that it was not homogeneous. The second portion was fine, but coarser than before. The third portion consisted of yellow liquid with some clots—quite coarse; the gastric juice was no longer diluted by excess of milk.

Experiments with Cereals.—Whatever be the part played by barley water in the stomach, it has made good a place in infant feeding, which indicates that benefit is derived from its use. But it seems probable that any such benefit is largely neutralized by the great proportion of starch which all cereals contain and which the infant economy is ill adapted to digest.

It is true that infants' foods may be bought in which the starch has been dextrinized by heat; but these are expensive. The object was then to devise a household process for preparing at a minimum cost, and with materials everywhere available, a digestible food containing with the albuminoid constituents of the grain carbohydrates in a soluble form, and but little of the insoluble starch. At the same time excess of sugar was to be avoided. This necessitated the conversion of the starch into dextrin, or into dextrin with a moderate proportion of maltose. Attempts to dextrinize the starch by heat showed that this method is not adapted for household use. Barley cakes baked many hours yielded only 23·3 per cent. of soluble matter. Rusks ("Zwieback") as bought were further baked, but only 16 per cent. could be made soluble. To facilitate the dextrinization by providing an acid, barley cakes were made with buttermilk and well baked, but the soluble matter was then only 20·07 per cent. Rusks moistened with buttermilk and baked at 120° C. yielded 18·88 per cent. of soluble matter.

These results necessitated a resort to diastase as the converting agent. O'Sullivan has shown that maltose and dextrin are the only products of the action of diastase on starch, and that the proportion of maltose to dextrin depends on the temperature. This proportion may be kept down to about eighteen per cent. by employing a temperature just below that which destroys the diastase and by stopping the action before the diastase converts the dextrin first formed into maltose. To adjust the temperature, hot and cold water were mixed in varying proportions. The temperature of the hot water was the highest which can be attained in the inner vessel of an ordinary double boiler of tin or enameled iron when the water in the outer vessel is kept boiling; this temperature does not vary much with the size of the boiler and is about 91° C.

The diastase was allowed to act on gruels made with starch, with wheat flour, with barley meal, and with oatmeal. The line of action, the quantity of water, and the temperature (proportion of hot to cold water) were varied, and more than twenty analyses were made to determine the proportion of soluble matter and of maltose formed in each

case. As the result of these experiments a most simple process was arrived at, by which in any kitchen a cereal food may be made containing three fourths of the solid matter in a soluble form and having more or less sugar (maltose) as desired.

For a food containing about one third of the solid matter in the form of maltose, the following recipe may be used:

RECIPE I.—Materials.—Wheat flour or barley meal, two ounces (two tablespoonfuls heaped as high as possible); water, fifty-six ounces (a quart and three quarters); extract of malt, half a teaspoonful or a small teaspoonful.

Process.—With thirty ounces (a scant quart) of the water make the flour into a gruel, boiling ten minutes in a double boiler. Take out the inner vessel and add the rest of the water cold, the malt extract being dissolved in the last few ounces added. Let it stand fifteen minutes. Put back the inner vessel and heat again in the double boiler fifteen minutes. Strain through a coffee strainer of wire gauze.

If for any reason it is desirable, and in cases of diarrhœa, to give a smaller proportion of maltose, the following recipe is used, and we get a food containing only one fourth of the solid matter in the form of maltose:

RECIPE II.—Materials as in Recipe I. Proceed as before, but reserve only one pint of the water for adding cold. After adding the cold water with the malt extract dissolved in the last few ounces of it, let it stand only three minutes instead of fifteen minutes. Then heat ten minutes in a double boiler and strain.

To make the gruel well and quickly, beat the flour with very little water. A little beating with little water is better than much beating with much water. Beat smooth, therefore, while the paste is still almost a dough; then add cold water to make a thin paste, and to this add the rest of the first part of the water boiling hot, with stirring. If these directions are followed, very few lumps will remain on the strainer; in fact, only about five per cent. of the meal need be lost in this way. The water in the outer vessel of the double boiler must be kept boiling throughout. Whichever recipe is followed, the food should be taken mixed with milk.

Digestion Tests.—*Cæteris paribus*, the more of a food is dissolved in the stomach, the more digestible is that food said to be. Therefore if we find in the stomach contents, after giving milk with the malted food, a larger proportion of soluble matter than when milk is given with unmalted food (due allowance being made for the larger proportion of soluble matter in the malted food itself), then we may say that the malted mixture is the more digestible of the two. In order to test this, experiments were made with three infants and the following results were obtained:

Ratio of Soluble to Total Matter in Stomach Contents:

	With Malted Food.	With Unmalted.
Subject 1.	0·65	0·58
" 2.	0·74	0·61
" 3.	0·58	0·64

The difference is appreciable (later results indicate that this was due to the short time allowed for digestion, which

TABLE II.—*Showing Proportion of Food found in Stomach after Various Periods of Digestion.*

A dash (—) under diastase indicates that none was given. A + indicates that the diastatic extract was used in the proportion given in the receipt.

never exceeded a few minutes in the above cases). Experiments were next tried without the admixture of milk. A comparison was next made between the two foods without admixture of milk. The process now followed was this: The stomach of a healthy man was washed clean with lukewarm water—*i. e.*, the washing was continued till the water from the stomach ran perfectly clear. Then a definite measure of gruel containing a known weight of solid food was drunk in five equal draughts with an interval of a minute between each draught. After a certain time the stomach was again completely washed; the washings were made to a given volume. The total solid matter and the dissolved matter were determined; the difference gives the matter undissolved. Experiments were made with three men, all free from any disorder of the stomach. The food prepared with diastase was given one day and the plain gruel the next. Although the amount of either food disappearing in a given time varied considerably, the results were sufficiently concordant to decide the question at issue.

Experiments 1 and 2, which were made without previous washing of the stomach (no food having been taken since the night before), agree fairly well with the others, showing that the digestive process is not rendered abnormal by previous washing. In the case of Subject No. 1 the amount found in the stomach was constantly greater when the diastase was omitted; the percentage of food taken which was left in the stomach after forty minutes being, without diastase, 52·02; with diastase, 29·2. This means that of a hundred parts of food taken, 100 — 52·02 or 47·92 were absorbed in the one case and 100 — 29·2 or 70·8 in the other; so that with the diastase nearly half as much again was absorbed as without it. Of the solid matter found in the stomach, more than twice as much was found to be undissolved when the diastase was omitted as when it was used.

With Subject No. 2 a shorter time (twenty-four minutes) was given for digestion and no marked difference appeared between the two foods; but when the time of digestion was extended to forty minutes the malted food again asserted its superiority, the amount of this unabsorbed by the stomach being only one third the amount of the plain food unabsorbed. In the case of Subject No. 3 the difference in favor of the malted food was made manifest in twenty-five minutes. In every case, therefore, digestion was more rapid with the malted than with the unmalted food. Thus the physiological evidence confirms the chemical evidence in favor of the food prescribed. Finally, clinical experiments with the soluble food, made according to Recipe No. 1, have given as good results as any system of feeding employed at the babies' wards of the Post-graduate Hospital, as detailed in the accompanying paper by Dr. Chapin. It is intended to employ the method of quantitative stomach washing in other cases, as it seems adapted for testing foods and digestive ferments in general.

July 9, 1893.

Yellow Fever in Brazil.—"The British Consul at Santos, in a recent report, states that yellow fever has been present in Santos, Brazil, for the last five years. It has varied in intensity from time to time, but has never disappeared. The mortality among seamen during the height of the pestilence last year was enormous, and as all who died were buried within two hours, it was practically impossible to trace individuals. In many cases no register was kept even of their names. It is known, however, that men were dying for weeks at the rate of thirty to forty a day. At the time of the consul's report there were between two and three hundred cases of yellow fever in the hospitals. The danger was considerably aggravated by the fact that seamen during their enforced stay in Santos have every facility to obtain a very cheap and injurious form of rum called cascaca, and are thus encouraged to live a disorderly life. Recent regulations, however, have considerably alleviated their condition, since they are now permitted to be discharged from the ships on which they arrive, and to take ship on outgoing vessels at the first opportunity. The consul also states that small-pox is extremely prevalent in Santos."—*British Medical Journal*.

MALARIAL FEVER IN INFANTS AND CHILDREN, FROM A STUDY OF THE PLASMODIUM MALARIE.

By HENRY KOPLIK, M.D.

THOUGH malarial fever in the adult has been one of the most favored themes of investigation in recent years, there is little or no work constructed upon modern data which treats of the disease as it occurs in children. The discovery of Laveran in 1880 and the immense field of knowledge opened up by it has not been utilized in the special field of diseases of children. It is difficult to account for this. The literature of malarial fevers and the *Plasmodium malariae* is too vast to attempt its review within the limits of this article, and such a review would serve no ulterior purpose. Laveran, Golgi, Marchiafava and Celli, Giuanieri, and in our country Osler, Councilman, and James, have drawn in their train no less than two hundred and fifty writers upon the *Plasmodium malariae*, as can be seen by consulting the literature recently collected by Mannaberg.

Mode of Investigation.—It has been the custom of the writer, in all cases of suspected or real malarial disease which have presented themselves in his practice within the past two years, to examine the blood with a view to making a diagnosis. In this way a large number of cases have been subjected to study and been proved to be not malarial infection, but various other diseases, with prognoses of slight to serious moment. Of this large material the cases which accompany the paper have been sifted. The temperatures, spleen, and general status have all been carefully noted. It was of interest to see how closely certain infantile maladies could simulate malarial fever. The various methods of blood preparation—Laveran, Plehn, Marchiafava, and Celli—have been tried by the author. The following method was finally adopted as yielding uniform and invariable results: The blood in most cases was obtained from the finger tip by puncture; in exceptional cases from the spleen by means of a clean hypodermic exploring needle. The blood was examined when possible in a fresh condition by placing a drop on a slide, covering with a cover glass, and without a heated stage, studying under the microscope. This was followed as a diagnostic method, and in a busy dispensary or clinic is not always feasible. In such cases, where time is lacking, the blood is spread rapidly upon a dozen or eighteen cover slips by the Ehrlich method and with the forceps used by him for this purpose. The blood is allowed to dry in the air protected from dust. The blood is then placed upon the Ehrlich brass plate and heated for an hour or an hour and a half. The cover glasses are then stained in a very dilute solution of methylene-blue. Eosin is not used, as some varieties decolorize the blue and thus introduce an element of uncertainty. The above method has the advantage of simplicity, and with a little practice is easily attained and absolutely reliable. The blood is heated at the Ehrlich temperature above the boiling point on the plate (120° C.). The variety of dye is important; some blue does not stain. Grüber's powder blue, soluble in alcohol, is used. A few drops of the saturated solution in alcohol are added to an ounce of water. The cover glasses should not be deeply

stained, as then certain pictures are lost. They are repeatedly washed in water and then dried without heat in the air. Heat decolorizes. By this method the blood cell is well hardened and its protoplasm and hæmoglobin stained more certainly than when hardened with alcohol, sublimate, or osmic acid. If desired, also part of the specimens may be stained by the Ehrlich anilin methods, to study other appearances, if present. The red blood-cells in malarial cases show the plasmodium in blue, the protoplasm as yellowish-green or colorless rings if anæmic, as the case may be. If the Ehrlich dyes are used—aurantia, orange G., etc., preferably the solution in glycerin of eosin, indulin, and aurantia—the plasmodium does not stain, but the hæmoglobin of the red blood-cell is stained in shades of varying intensity.

Occurrence.—Of a very large number of cases examined by the writer for evidences of malaria in the blood which exhibited certain clinical signs, large spleen, an intermittent, remittent, or irregular temperature, anæmia, only a comparatively small number remain stamped by the blood appearances as malarial disease. This is the more interesting, as the methods of investigation were uniform and carefully carried out. In all the cases which were fixed by the blood examination to be malarial, a history of sojourn outside the city limits in the adjacent country districts could be easily obtained. Some of the cases contracted the disease in foreign lands. The manifestations of malaria in the American cases appeared shortly after the children had returned to the city. In only one case, in which the mother was a very intelligent German and the child aged nine years, the chills set in fully six months after the return to the city. In no case was there a history which could be verified by the study of the blood, etc., in which the malarial fever was contracted in this city. In this respect my observations agree with those of Dr. James, who in a very large series of adult cases failed to find malarial fever an indigenous or even sporadic disease in New York. My own material, ranking among the most extensive in this city, includes cases from all parts of the city, as well as that of the immediate vicinity of the dispensary. No less a clinician than Alonzo Clark, whose equal the city will rarely see, taught in his day that where the soil had been disturbed by excavations in the city streets, intermittent fever was apt to appear in adults. I have had sick children within the past few years from districts where extensive excavations were in progress, but in no case could I trace the malarial disease, if present, to this cause, or if thought to be present, it was excluded eventually by careful study. I conclude that there may have been a change in the subsoil of the city in recent years resulting from density of settlement and more perfected drainage. Malarial fever in children must be regarded as not indigenous in New York city to the extent formerly supposed.

Cases and Types.—The cases of malarial intermittent fever seen by the author range from ten months to nine years of age. Cases of very tender infancy may differ in manifestations from those of later childhood. But while many cases of later childhood resemble in every way those of adult life, yet in some older children this is scarcely so,

and each case must be studied for itself. This study supports the view that in children and infants the manifestations of malarial poison are varied.

If the most recent text-books and articles treating of malarial fevers in children are consulted, it will be seen that the statement is invariably made that the type of fever in these subjects is quotidian, tertian, and quartan, in the frequency stated. The type of fever may, of course, vary with the locality and season of the year. I need but briefly refer to the quotidian parasite of Marchiafava and Celli and the tertian and quartan parasites of Golgi. In all my material, drawn from most removed spots, I have seen the quotidian parasite of Marchiafava and Celli and the quartan parasite of Golgi but once (Case XIV from Asia Minor). The investigations of Golgi are of such interest in this connection as to justify brief notice here. Golgi (*Fortschritte d. Med.*, 1889) concluded, from a study of endoglobular pictures, that the tertian and quartan types of intermittent fever were caused by two distinct species of plasmodia malarie. The one (tertian) ripens or runs its course in the red blood-cell in two days, the other (quartan) requiring three days for its full development and sporulation. In the parasite, therefore, he was able to recognize the type of fever, and even the time at which a chill was imminent. This latter was done by noting the stage of development of the parasite. In pure types of fever, either tertian or quartan, one generation of plasmodia, all in about the same stage of growth, would predominate. In those cases of tertian where the paroxysms were of daily occurrence, several generations of parasites, each with a different cycle of development, were found in the blood. The same was true of irregular types of fever with the tertian parasite. The same argument could be applied to the quartan fevers. If more than one generation of parasite existed in the blood in a tertian case, the fever could become quotidian with daily paroxysms due to the ripening of distinct sets of parasites on different days, each set of parasites taking forty-eight hours to mature; thus 1 0 1 0 1 0 1 0 1 0 1—pure tertian, one parasite; 1 2 1 2 1 2 1 2 1 2 1—double tertian, two parasites, giving quotidian paroxysms.

In quartan we may have the following combinations: 1 0 0 1 0 0 1 0 0 1 0 0 1—pure quartan, one parasite; 1 2 0 1 2 0 1 2 0 1 2 0 1—double quartan, two parasites; 1 2 3 1 2 3 1 2 3 1 2 3 1—triple quartan, three parasites, giving quotidian chills (Mannaberg).

It will be seen that no quartan combination of parasites can cause pure tertian types of paroxysms, though we may have quotidian chills, and in this respect it may resemble the tertian fever.

Marchiafava and Celli described a mild quotidian type of fever as caused at least in the district studied by them by a small parasite with very little pigment. James found most of his cases in the first thirty examined and published by him to be tertian types caused by the tertian parasite. He had never met the quartan parasite and its type of fever. All the writer's cases in children, with the exception of two, were marked by the presence of the tertian parasite. One of the exceptional cases had lasted some time, Russian in origin, and the blood showed the

half-moons and crescents of Laveran; rarely was a full tertian parasite found. The other case was a quartan intermittent containing in the blood the quartan parasite of Golgi. My material places the tertian fever as first in frequency. It must be remembered that in tertian cases quotidian or daily paroxysms occur. This was so in several of my cases. The older authors, in placing the quotidian type of paroxysm as first in frequency (Hench), were correct as to occurrence of paroxysms, but not really correct as to nomenclature of the fever, for it will be seen they may have had the tertian parasite to deal with. It is also possible that in many of these cases the daily paroxysms did not occur at the same time exactly if such had been noted.

The Plasmodium Malarie.—It is not intended to give a description of the *Plasmodium malarie* here, as this has been well done by others, but merely to point out, as has been done above, that the various types of fever (tertian, quartan, quotidian) may be caused by distinct species of parasites differing decidedly in properties (mild, malignant) from each other. The doctrines promulgated by Golgi and his followers differ from those of Laveran, who thought that all intermittent or malarial fevers were caused by the same parasite, which was polymorph and varied in its manifestations in different spots and individuals. In children the writer has observed that it is quite common to obtain a history showing that the paroxysms at first were purely tertian; after a time the little patients would develop double tertian, or what the older authors called quotidian chills. In these cases the chills occur at the same hours, only every other day, or the chill of one day is not of the same series as that of the day immediately following, but removed by one day (two sets of parasites). Frequently we will obtain a history of pure tertian chills every second day at the same hour. If many of such children are examined on the day on which they are supposed to be exempt from fever, it will be observed that they will exhibit a very mild febrile movement, half or three quarters to one degree above the normal in the rectum (Case XII). On closely questioning the parents or patient, it will be found that on these days at a certain hour the children complained of lassitude or headaches. If the blood of these children is examined in the interval, the parasites will be found in varied stages of development. We have here to deal with a form of double tertian fever in which either one set of parasites runs an abortive course of development and sporulation or, when sporulation occurs, it is not sufficiently abundant to cause a chill. The temperature in such cases can be remittent in curve. Though at first parasites may exist in the blood in one generation giving pure tertian, we are impressed, after a study of these cases, that these pure types give way to double tertian fevers after having lasted a short time. In quotidian paroxysms of chills and fever we must be prepared to meet the tertian parasite in children. Further study in other districts will decide how frequently, if at all, the quotidian parasite of Marchiafava and Celli is found in children in this country. The quartan parasite also needs further study in children.

Condition of the Blood; Tertian Parasite.—In pure ter-

tian fever of recent development (Case XV) an examination of the blood a few hours after the chill showed almost exclusively young spore forms in shape of non-pigmented rings in red blood-cells only; rarely was a fully developed plasmodium, apparently delayed in sporulation, found. In some specimens groups of sporula were found free. We can theorize that the delayed form might in time become the leader of a separate generation of parasites. In double tertians, examined between the paroxysms, forms of plasmodia in varied stages of development were found. For convenience they are grouped—

A. The colorless, irregularly oval-shaped plasmodium, without pigment, having a rapid amoeboid movement.

B. The same bodies as A, but larger, containing rods and fine pigment granules. The rods and granules were fine, resembling minute bacilli, having with the amoeboid movement of the plasmodium a rapid oscillatory motion, at times aggregating toward the center of the plasmodium, at others collecting at the periphery. Some granules finally arranged as broken rings in the plasmodium. In this young plasmodium the red blood-cell envelope could be made out.

C. Full-developed plasmodium having structure same as above but larger.

D. White blood-cells, varied in shape, having within their cell body granules and rods of pigment (melaniferous leucocytes). These white blood-cells were not seen to perceptibly change form (without heated stage).

F. Rarely small round spherical bodies with the so-called flagella were found. Only met in two cases.

Stained Specimens contained: A. Hyaline bluish-stained bodies, ring-shaped, inside the red blood-cell. They contained generally at the periphery a darker speck, the nucleus (young native forms).

B. Older forms, bluish-stained, irregular-shaped, no pigment.

C. More advanced forms shaped like a crescent, the points of the crescent inclosing a hyaline, structureless, spherical mass (nucleus), the body of the crescent just showing the indications of pigment. The red blood-cell distinctly swollen above normal size.

D. More advanced forms with or without nucleus, sometimes with vacuoles or empty openings which did not stain; pigment more abundant. Red blood-cell easily made out as anæmic ring, much swollen above normal size.

C. Fully developed plasmodium ready to sporulate; pigment dividing the plasmodium into districts; at other times this not found.

E. Free groups of sporula (after a chill).

F. Spherical hyaline bodies with flagella, rare in dried specimens; found only twice in fifteen cases.

G. White blood-cells containing pigment.

H. Red blood-cells with irregular bluish streaks.

I. Red blood-cells which stained slightly blue and were dotted with bluish specks.

The half-moons of Laveran were found in three cases of tertian accompanying the regular parasite. In a fourth case they were found in the blood only after the same had been repeatedly examined by stain. This was a chronic case and should teach that in these cases where the cres-

cents and moons are found almost exclusively the blood must be repeatedly examined. They have, as we know, in adults persisted a long time into convalescence (Laveran, Mannaberg).

The Ehrlich method does not stain the plasmodium, but it demonstrates very clearly the anæmia of the red blood-cell and its lack of hæmoglobin in proportion to the amount of pigment contained. The larger the plasmodium and the more pigment, the more anæmic the erythrocyte. *Nucleated red blood-cells* were found in two cases in which the anæmia was profound. Eosinophile cells were in some cases so few as to be found with difficulty; in others they were more numerous. In no case increased. The multinuclear leucocytes seemed to be the predominating form of white blood-cell. The case of quartan fever coming under my observation contracted the fever in Asia Minor, where the patient was born. The fresh blood, examined in the intervals of the chills, showed, with a temperature of 99.8° F. in the rectum—

A. Free granules of pigment in the blood, larger than in the tertian cases and irregular in shape. The pigment sometimes found alongside of transparent small round bodies or spores. Sometimes fibrin threads started from the pigment.

B. White blood-cells containing pigment (melaniphorous leucocytes).

C. The colorless plasmodium inside the red blood-cell, having a slowly changing movement.

D. Peculiar brassy-colored shrunken red blood-cells with a small mass of pigment at one spot.

E. Fully developed parasites, the exact counterpart of the photographs published by Golgi of the quartan parasite (*Zeitsch. f. Hygiene*, Bd. x, Heft 1), not seen by me in any of my tertian cases. The "daisy-shaped" forms. The pigment in form of a dark-brown central mass, irregular and large. The finer pigment rods and granules of the tertian forms not seen.

The figures (microphotographs) show the *Plasmodium malariae* of the tertian variety in various stages of development in the same specimen of blood. Taken in the interval of the chills.

FIG. 1.—Young native parasite inside red blood-cell with nucleus, no pigment. $\times 1,000$. Ehrlich dried specimen stained with methyl-blue. Zeiss immers. $\frac{1}{2}$, projec. ocular 4. Calcium light.

Clinical Course.—It is intended only to touch upon those points which appeared of interest in the author's cases as having been accompanied by the *Plasmodium malariae* in the blood of the patients.

FIG. 2.—Young parasite inside swollen red blood-cell, the tips of the crescent holding the hyaline nucleus. $\times 1,000$. Same as above in stain and preparation.

Incubation Stage.—Some children while living in a malarious district do not manifest any of the classical symptoms of malarial fever. At first there are absolutely no objective signs. The febrile movement must be low, coupled with a slight anæmia not noticeable at first to the parents. After coming away from the infected district the chills appeared in some of my cases in from eleven days to two to four weeks. Close questioning failed to discover illness of a marked character while at the malarial spots. In one case, in which the mother and the patient, nine years old, both were intelligent, the chills appeared fully six months after leaving the infectious district. Here the incubation may have been prolonged, or, what is more probable, the poison may have manifested itself months previous in the form of masked symptoms since forgotten.

FIG. 3.—Fully developed parasite, rods of pigment arranged in round areas, nucleus indicated by opening, also vacuoles. $\times 1,000$. Stain, preparation, and lens as above.

Chills.—In one case my attention was called to an infant, aged ten months, whose sister was under my care for malaria. The infant was extremely anæmic. There was

no regular febrile curve, and at no time were there chills. The spleen was large. The parents had noticed the pallor, but had not considered the infant ill, and did not ask advice about its condition. The *Plasmodium malariae* was found in the blood abundant and in various phases of development.

In another infant the chills manifested themselves in a blueness and coldness of the surface coming on at a certain hour of the day. This was followed by a febrile movement and sweats. In another case, a grown boy, the paroxysms were sometimes indicated by headache and lassitude coming on at a certain hour.

Typical chills were present in most cases. In no case was there eclampsia.

Fever.—I have elsewhere called attention to a set of cases in which the pure tertian paroxysms are accompanied by a low grade of continued fever on the day upon which the patient is supposed to be exempt. On this day, at a certain hour, lassitude and headache will indicate the duplicate chill. The temperature upon these days, even in the rectum, is only slightly raised—a half to one degree. It seems as though in these cases we have a marked attack of intermittent alternating with the classical paroxysm.

Spleen.—In all but one case the spleen was larger than normal, and could be palpated below the border of the ribs. In the case in which the writer found only oval and crescent-shaped forms of plasmodia the size of the spleen was enormous. This was a chronic case. In the case in which the spleen was not felt below or behind the ribs (Case XV) it could be mapped out by percussion. In this case, in which the patient was seen on the first day of the paroxysms, the spleen was not at all as large as we find it in children. Here the difficulties of diagnosis would be increased by an omission of a blood examination. At this early day, without perceptible enlargement of the spleen, the *Plasmodium malariae* was found in the blood.

Anæmia, which was present in most cases, persisted for a long time after the spleen could not be felt below the border of the ribs.

Repeated Attacks and Relapses.—A few of my cases suffered from a number of attacks of intermittent before coming under observation. In these cases, notably the quartan case, the anæmia was not very profound, nor was the spleen markedly larger than in those cases in which there was a history of a single attack alone. Children thus seem to bear the malarial poison well in certain districts, and must be long sufferers before exhibiting profound effects. What the parents call a number of attacks are legitimately assumed to be relapses. Excluding two cases, including the quartan case, many cases acted thus: The parents, after having dosed the children with quinine, noted the disappearance of the paroxysms and suspended treatment. In such cases the chills would return after an interval. How long this interval can be may be seen from the following well-observed case: An infant, aged fifteen months, was treated by me for malarial fever, and the treatment continued until not only the chills disappeared and the spleen returned to the normal, but arsenic was administered for a long period until all anæmia had disappeared.

The infant was seen at intervals, and continued healthy. Fully nine months after the original attack, without having returned to the malarious district, the infant became anæmic and manifested tertian paroxysms, with the reappearance in the blood of the plasmodium. Such cases can only be explained by assuming the long resistance of spores to the action of quinine and arsenic. Laveran and Mannaberg found crescents in the blood long after convalescence was established.

Differential Diagnosis.—The study of the blood and allied diseases, especially in infancy and childhood, has advanced so much within the past decade that the diagnosis of malarial disease to-day presupposes an intimate knowledge of the diseases of the blood and spleen as well. The enlargement of the spleen, upon which so much stress was formerly laid, is present in malarial poisoning it is true, but it has been shown in Case XV to be absent at least at the outset of the malady. Enlargement of the spleen is also present in other diseases in which there are remittent curves of temperature, such as typhoid fever and chronic enterocolitis. In rhachitis we find a number of cases with enlarged spleens which are apt to exhibit transient temperatures due to dyspepsias. Severe chronic anæmias, with or without rhachitis, show large spleens. I need only refer to that interesting condition of infancy known as anæmia infantum, pseudo-leucæmia, or von Jaksch's disease, examples of which have been recently published by the writer in the *Archives of Pediatrics*. In one of these cases, which is still alive and doing well after a year of observation, the enlarged spleen was combined with a remittent curve of temperature. The author has met cases of the infectious fevers, such as varicella, which at the outset give a history of repeated chills and show enlarged spleen. Cases of congenital syphilis will at times show not only an enlarged spleen, but enlarged liver also, and this in cases which have been observed from birth. It seems to the author that in addition to our history we must examine the blood in each case for a crucial

exclusion diagnosis. In cases of marked intermittent fevers, obscure symptoms (intermittens larvata), such as have been published by Filatow, examination of the blood gives us the only crucial test. The cases in which a negative result is obtained and in which the plasmodium is difficult of discovery are chronic cases with a continued remittent or irregular temperature curve; here the plasmodium appears mostly as half-moons and crescents of Laveran, and many specimens of blood may be examined without their discovery, such as Case IV. Quinine administered in even moderate doses will drive the plasmodium out of the circulation in children even after twenty-four hours of exhibition of the drug. With correct technique and the observance of the above precautions it is difficult to conceive of negative cases.

Treatment.—The mode of treatment of intermittent fevers adopted by me is simple and will scarcely present anything novel.

Quinine in the form of the bisulphate or hydrochloride is the most favorite prescription. Children will bear larger doses than adults and should have it thus. The paroxysms are anticipated by two hours by the first dose, and the second dose is given at the time of the paroxysm; thus the drug is exhibited only twice daily. Quinine will eliminate the paroxysms, but in some children improvement ceases there, and arsenic, in the form of Fowler's solution, must be administered with the quinine. After the spleen ceases to be felt below the border of the ribs quinine is stopped and arsenic is continued until all signs of anæmia have disappeared; this, in some cases, is quite an extended period of time. Inasmuch as in children preparations of iron are not so well borne and the intestinal processes are much disturbed by its exhibition, it should be withheld. If exhibited at all for the anæmia, it should be done through the agency of the vegetable preparations, the mannitate, or those preparations which contain minimal quantities of manganese.

Epitome of Cases.

Case.	Age.	Sex.	Number of the attack.	Duration of attack.	Presence or absence of chill.	Type of paroxysm.	Species of parasite.	Spleen.
I.	9 years.	Female.	First.	2 weeks.	No chill.	No type; irregular.	Tertian.	Large.
II.	15 months.	Female.	First.	3 weeks.	Yes.	At first tertian, now quotidian.	Tertian.	Large.
III.	10 months.	Female.	First.	?	None.	Irregular.	Tertian.	Large.
IV.	3 years.	Female.	First.	4 months.	None.	Irregular.	Crescents and tertian.	Very large.
V.	8 years.	Female.	First.	3 months.	Yes.	Tertian.	Large.
VI.	9 years.	Male.	First.	10 days.	Yes.	Tertian.	Tertian.	Large.
VII.	6 years.	Female.	First.	Yes.	Tertian.	Tertian.	Large.
VIII.	22 months.	Male.	First.	7 days.	None.	Quotidian or double tertian.	Tertian.	Large.
IX.	5 years.	Male.	Second.	3 days.	Yes.	Tertian.	Tertian.	Large.
X.	4 years.	Female.	First.	3 weeks.	Yes.	Tertian.	Tertian.	Large.
XI.	3½ years.	Male.	Second.	2 months.	None.	Pure tertian.	Pure tertian.	Very large.
XII.	9 years.	Female.	First.	5 days.	Chill only every other day; fever on the day intervening.	Double tertian; an attack not accompanied by a regular chill.	Tertian.	Large.
XIII.	8 years.	Female.	First.	4 weeks.	Yes.	Tertian.	Tertian.	Large.
XIV.	5 years.	Male.	Several.	weeks.	Yes.	Double quartan.	Quartan.	Large.
XV.	3½ years.	Female.	First.	12 days.	Yes.	Tertian.	Tertian.	Normal in size.

NOTE.—Case XII, on the day when patient was supposed to be well, temperature 101.2° in rectum (marked attack without chill).

TETRA-ETHYL-AMMONIUM.

A NEW SOLVENT FOR URIC ACID DISCOVERED AT THE EDISON LABORATORY.

By FREDERICK PETERSON, M. D.,

INSTRUCTOR IN NERVOUS AND MENTAL DISEASE;
COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK;
PROFESSOR OF NERVOUS DISEASES, UNIVERSITY OF VERMONT.

DURING my researches into the subject of the introduction of drugs into the body through the skin by electricity (cataphoresis) the question of the advantages of such a method arose in connection with the use of local solvents, as well as of local anesthetics. Local solvents might be useful in the removal of gouty and rheumatic topi and swellings. At the same time that I was making investigations into the subject of cataphoresis Mr. Thomas A. Edison undertook some work in the same line, and particularly in relation to rheumatic joints. These experiments are now familiar to the profession. It was evident, however, that none of the salts, such as those of lithium, was sufficiently effective in dissolving uric acid and urates, and it became necessary to seek a new solvent that would better answer the purpose. Mr. Edison then set for himself the problem of finding the best chemical solvent or solvents for uric acid. He possesses the largest collection of liquid solvents in this country, having every solution that can be permanently kept. He prepared several hundred of the smallest glass phials, each holding about two cubic centimetres, corked and labeled. In each he dropped a small quantity of powdered uric acid as obtained chemically pure from Germany and then filled up the phials each with one solution. After shaking them up he set them aside for periodic examination. Only two of these phials showed that the uric acid had dissolved—that is, with anything like readiness. The two successful solutions were those of neurine and tetra-ethyl-ammonium. On repetition, these were found to dissolve uric acid quite freely. I have compared myself the relative values of tetra-ethyl-ammonium and piperazine, finding that the former is much more effective than the latter as a solvent for urea, uric acid, and the like. I employed ten-per-cent. solutions of each for my experiments. Urate of sodium removed from the knee of a patient dissolved readily in both neurine and tetra-ethyl-ammonium. Mr. Edison determined to follow up the use of the latter as being a definite inorganic compound, and the following experiments were made under his directions at the Edison Laboratory: Two rabbits were selected and the hypodermic injections were made as below:

December 1st, 0.25 c. c. of a one-per-cent. watery solution of tetra-ethyl-ammonium in the right ear of rabbit No. 1.

December 2d, 0.5 c. c. of same in left ear of same rabbit.

December 3d, 0.5 c. c. of same in left ear of rabbit No. 2.

December 4th, 0.75 c. c. of 1.7-per-cent. solution in right ear of rabbit No. 2.

December 6th, 0.75 c. c. of three-per-cent. solution in right side of rabbit No. 1.

December 8th, 0.75 c. c. of three-per-cent. solution in right side of rabbit No. 2.

December 10th, 1.0 c. c. of three-per-cent. solution in four pills by mouth in rabbit No. 2.

No bad effects followed any of these administrations. Mr. Edison turned the whole matter over to me for further investigation. It seems that both neurine and tetra-ethyl-ammonium are normal constituents of the bodies of animals, and it may be that the diseases in which urates are produced and accumulated in the system are due to a deficiency of what seem to be normal elements of our structures. Now it became necessary to make some observations in human beings, and being generously supplied with the drug by Mr. Edison, it not being obtainable in this country, I have established its dosage and apparent usefulness, and now give it to the profession for such further experiment as may seem justifiable after the above facts. I trust that those physicians especially who have much to do with uric-acid calculi, gouty and rheumatic conditions, and the like, will make use of what seems to be a valuable addition to the pharmacopoeia, and publish the results of their treatment. It is important to bear in mind that tetra-methyl-ammonium is poisonous, giving rise to symptoms similar to those of curare, whereas tetra-ethyl-ammonium may be employed with safety. Through the courtesy of Dr. S. T. Armstrong, attending physician at the Harlem Hospital, the tetra-ethyl-ammonium in a ten-per-cent. solution was tried upon three patients whose histories are given below:

CASE I.—T. O'C., aged twenty-nine years; single; United States; occupation, laborer. Admitted on February 27, 1893, at 9.15 P. M. Diagnosis: Acute articular rheumatism and mitral stenosis.

History.—Family history negative. Previous history, usual diseases of childhood. Patient states that he has always enjoyed good health up till four years ago, at which time he had his first attack of rheumatism. Since that time he has had three attacks. Between attacks felt in his usual health, as far as the rheumatism was concerned. He has been in a hospital on two different occasions for the above complaint. Present history: This attack could not be assigned to any particular, to cold or wet. Sickness dates back one week previous to admission. He first experienced a slight chill, followed by a slight fever, and the next day noticed that there was some stiffness in the knee joints. In a short time they became red, hot, swollen, and very painful, especially in attempting any movement. This condition of things remained about the same up till the time of admission. Examination in hospital showed that, besides the knee joints, there was some stiffness in both ankles, and within two days they became involved like the knees. Examination of heart showed a mitral presystolic murmur, heard only at the apex and not transmitted (mitral stenosis).

February 27th.—Temperature, 100.8°; pulse, 88; respiration, 26 (on admission).

Treatment.—Tetra-ethyl-ammonium, ten-per-cent. solution, ten minims t. i. d.; the temperature, pulse, and respiration taken before and after giving solution.

February 28th, 3 P. M.—Temperature, 101°; pulse, 88; respiration, 18. 4 P. M., temperature, 101.4°; pulse, 88; respiration, 22.

March 1st, 8.30 A. M.—Temperature, 99.2°; pulse, 76; respiration, 20. 9.30 A. M., temperature, 99.2°; pulse, 76; respiration, 20. 12 M., temperature 99.8°; pulse, 76; respiration, 20. 1 P. M., temperature, 99.8°; pulse, 84; respiration, 20. 5.30 P. M., temperature, 100.2°; pulse, 84; respiration, 20. 6.30 P. M., temperature, 100°; pulse, 84; respiration, 20.

2d, 8.50 A. M.—Temperature, 98.8°; pulse, 84; respiration, 20. 9 A. M., temperature, 98.8°; pulse, 84; respiration, 18.

1.30 P. M., temperature, 99° 6'; pulse, 86; respiration, 28. 2.30 P. M., temperature, 99° 6'; pulse, 96; respiration, 30. 9.55 P. M., temperature, 101° 4'; pulse, 96; respiration, 36. 10.55 P. M., temperature, 100°; pulse, 84; respiration, 20.

3d, 8.30 A. M.—Temperature, 100° 6'; pulse, 88; respiration, 28. 9.30 A. M., temperature, 100° 6'; pulse, 84; respiration, 24. 12.10 P. M., temperature, 100° 8'; pulse, 84; respiration, 20. 1.10 P. M., temperature, 101° 2'; pulse, 97; respiration, 27. 6.15 P. M., temperature, 100° 8'; pulse, 84; respiration, 24. 7.15 P. M., temperature, 100° 4'; pulse, 84; respiration, 26.

4th, 8.30 A. M.—Temperature, 99°; pulse, 78; respiration, 20. 9.30 A. M., temperature, 98° 6'; pulse, 76; respiration, 20. 1.30 P. M., temperature, 98° 4'; pulse, 84; respiration, 18. 2.30 P. M., temperature, 99° 2'; pulse, 78; respiration, 18. 5.30 P. M., temperature, 98° 6'; pulse, 76; respiration, 20. 6.30 P. M., temperature, 98°; pulse, 84; respiration, 24.

5th.—Temperature, 98° 6'; pulse, 78; respiration, 18.

6th.—Temperature, 98° 2'; pulse, 74; respiration, 18.

7th.—Temperature, 99° 2'; pulse, 80; respiration, 20.

8th.—Temperature, 98° 8' to 99° 2'; pulse, 82 to 84; respiration, 22 to 24.

9th.—Temperature, 98° 2'; pulse, 68 to 78; respiration, 16 to 20.

10th.—Temperature, 98°; pulse, 82; respiration, 24.

Solvent solution suspended on March 5th. The rheumatic symptoms soon passed out of the ankle joints. The knees were slower to yield to treatment, as they had been unusually swollen and painful, there being a large amount of exudates in the joint. For four days previous to discharge the patient was able to be about the ward. At the time he went home the joints were restored to their normal condition, and the condition of patient was very good. The mitral stenosed murmur was indistinct, but still present.

Result.—Discharged, cured, March 10, 1893.

Urine Examination.—February 28th, amber; acid; specific gravity, 1.017; albumin, none; sugar, none. March 6th, amber; acid; specific gravity, 1.017; albumin, none; sugar, none. March 7th, 1 c. c. = 0.014 gramme urea. March 8th, 1 c. c. = 0.012 gramme urea. March 9th, 1 c. c. = 0.011 gramme urea. March 10th, 1 c. c. = 0.012 gramme urea.

Remarks.—In this case the rheumatic attack was of remarkably short duration—only one week after the beginning of the remedy. His doses were ten minims of a ten-per-cent. solution three times a day.

CASE II.—O. G., aged eighteen years; single; born in Germany; three years in United States; occupation, clerk. Admitted to hospital on March 14, 1893. Diagnosis: Acute articular rheumatism.

History.—Family history negative. Previous history: Always enjoyed good health, except the usual sickness incident to childhood. Present history: Four weeks previous to admission the patient states that he was exposed to wet and cold for some time, and he developed a severe "cold." A week after this he noticed some stiffness in the ankle joints, and they very shortly became painful, red, hot, and swollen. Patient being unable to continue about his work, then went to bed. At the time of his admission the ankle joints were about well, there being only some stiffness remaining. The day before he came into the hospital the knee joints became involved in the same way. There was no history of initial chill, and there was but slight fever.

March 14th, temperature, 99° 6'; pulse, 100; respiration, 29.

15th.—Tetra-ethyl-ammonium, ten-per-cent. solution, ordered five minims t. i. d. 11 A. M., temperature, 102° 2'; pulse,

100; respiration, 28. 12 M., temperature, 102°; pulse, 100; respiration, 22. 2 P. M., temperature, 102° 6'; pulse, 100; respiration, 28. 3 P. M., temperature, 102° 4'; pulse, 102; respiration, 20. 5 P. M., temperature, 102°; pulse, 100; respiration, 24. 6 P. M., temperature, 103° 2'; pulse, 112; respiration, 34. 9 P. M., five grains of antifebrin were ordered.

16th.—Temperature, 101°; pulse, 108; respiration, 28. 9.20 A. M., temperature, 100° 2'; pulse, 100; respiration, 28. 2 P. M., temperature, 102° 4'; pulse, 108; respiration, 32. 3 P. M., temperature, 102° 8'; pulse, 108; respiration, 28. 5 P. M., temperature, 101°; pulse, 100; respiration, 32. 6 P. M., temperature, 103°; pulse, 108; respiration, 26.

17th, 9 A. M.—Temperature, 101°; pulse, 88; respiration, 28. 10 A. M., temperature, 101°; pulse, 88; respiration, 28. 2 P. M., temperature, 102°; pulse, 92; respiration, 28. 3 P. M., temperature, 101° 4'; pulse, 88; respiration, 28. 5 P. M., temperature, 101°; pulse, 80; respiration, 26. 6 P. M., temperature, 101° 4'; pulse, 94; respiration, 26.

18th, 9 A. M.—Temperature, 100° 2'; pulse, 90; respiration, 24. 10 A. M., temperature, 100° 6'; pulse, 94; respiration, 26. 2 P. M., temperature, 101° 4'; pulse, 100; respiration, 28. 3 P. M., temperature, 101°; pulse, 100; respiration, 28. 4.30 P. M., temperature, 104° 4'; pulse, 96; respiration, 26. 5.30 P. M., temperature, 101° 4'; pulse, 94; respiration, 28.

From this time on the temperature, pulse, and respiration ran about normal, the solvent solution having no effect on them.

Results of examination of urine: March 17th, specific gravity, 1.021; acid; no albumin. March 19th, 1 c. c. = 0.025 gramme urea. March 20th, 1 c. c. = 0.02 gramme urea. March 21st, 1 c. c. = 0.018 gramme urea.

The patient improved rapidly under treatment, and was well at time of discharge.

Result.—Discharged, cured, March 22, 1893.

Remarks.—The patient was on five minims, three times daily, of the ten-per-cent. solution of tetra-ethyl-ammonium by the mouth for eight days, at the end of which time he was discharged recovered. The acute attack had begun some three weeks previous to the beginning of this treatment.

CASE III.—B. D., female, admitted December 19, 1892.

Diagnosis.—Acute articular rheumatism.

History.—Family history negative. Patient states that she has always had good health up till one year ago, at which time she had her first attack of rheumatism and was sick two months. She entirely recovered from it, and had no further trouble till her present sickness. Present history states that she had been sick three weeks previous to admission. There is no history of chill, fever, etc. States that she simply began to experience slight pain in the left hand, foot, and hip; subsequently these joints became swollen and painful and she was unable to move them, and any attempt to do so caused great pain. Within a few days all the joints of the extremities became involved in the same way; at the time she was brought in by ambulance she was almost helpless. From December 20th to January 2d temperature ranged from 98° to 100°; pulse, 80 to 100; respiration, 15 to 28. January 2d to January 6th, temperature 99° 2' to 100° 8'; pulse and respiration same. January 7th to January 20th, temperature, 98° to 100° 4'; pulse and respiration same. January 21st to February 7th, temperature, 98° 8' to 101°; pulse and respiration same.

Treatment.—Usual remedies, without effect from the day of admission to February 8th, when all were discontinued and she was put upon tetra-ethyl-ammonium—one to two minims of

the ten-per-cent. solution four or five times daily hypodermically. Thus given, it had no bad effect except in some places to produce tissue necrosis without abscess formation at the point of injection. There were no general effects upon the respiration, pulse, or temperature. After a few doses hypodermically it was given by the mouth in gradually increasing doses until sixteen minims of the ten-per-cent. solution was reached. This was continued until her discharge, March 1, 1893. Her improvement was slow and gradual, and for two weeks previous to her discharge she was able to be about the ward. The following examinations of the urine were made:

Union Examination.—February 7th.—Specific gravity, 1.001; acid; albumin, none; sugar, none.

8th.—Specific gravity, 1.012; acid; albumin, none; sugar, none.

10th.—1 c. c. = 0.005 grm. urea.

11th.—1 c. c. = 0.005 grm. urea.

12th.—1 c. c. = 0.005 grm. urea.

13th.—1 c. c. = 0.005 grm. urea.

14th.—1 c. c. = 0.125 grm. urea.

15th.—1 c. c. = 0.0125 grm. urea.

16th.—1 c. c. = 0.013 grm. urea.

18th.—1 c. c. = 0.001 grm. urea.

19th.—1 c. c. = 0.011 grm. urea.

These cases, while there was manifest improvement in them under the new treatment, are not brought forward as evidence of the value of the drug, but were used to determine dosage in human beings.

The doses by mouth that may be safely used are ten to twenty minims of a ten-per-cent. solution of tetra-ethyl-ammonium. Hypodermically it would be better to have a one-per-cent. solution and to inject not more than ten minims of this until assured that no deleterious effect upon the tissues is produced.

Tetra-ethyl ammonium: Hofmann (*Annalen der Chemie*, vol. lxxviii) obtained it by decomposing its iodide by moist AgNO_3 or its sulphate by baryta. It occurs in deliquescent hair-like needles. It absorbs CO_2 from the air. It is strongly alkaline, saponifying fats. Concentrated, it burns the tongue. It is as bitter as quinine. It has a caustic action upon the epidermis and an unctuous, alkaline feel when rubbed between the fingers. Its formula is NEt_4OH . It is not decomposed by the galvanic current. It forms numerous salts (sulphate, nitrate, phosphate, carbonate, hydrochlorate, hydrobromate, iodide, bromide) and beautiful double salts with platinum, gold, mercury, etc.

The ten-per-cent. solution may be safely employed internally in the doses already stated (ten to twenty minims three times daily), and it may be used hypodermically in one-per-cent. solutions. It may prove especially useful in the place of solutions of lithia salts when applied on positive galvanic electrodes about gouty joints or rheumatic tophi. The one-per-cent. solution may be used for cathartic purposes.

Changes of Address.—Dr. E. N. Bradley-Byström, to No. 132 West Fifty-eighth Street; Dr. C. B. Carter, to No. 36 West Fifty-ninth Street; Dr. J. F. Chmieleck, from Detroit to No. 212 East Seventieth Street; Dr. J. Clifton Edgar, to No. 54 East Thirty-fourth Street; Dr. Samuel E. Milliken, to No. 36 West Fifty-fifth Street; Dr. A. N. Strouse, to No. 72 West Fifty-fifth Street.

Dr. Oliver Wendell Holmes passed his eighty-fourth birthday in good health on the 29th of August.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, SEPTEMBER 16, 1893.

MEDICINE AS A CAREER.

DURING a recent after-dinner conversation between some physicians one of the party chided another because he said he had advised that a young man who had finished his collegiate career should take up the study of medicine. The critic intended that amiability rather than captiousness should be the reason for his protest against the possible acquisition by the medical profession of another member that took this calling as a career in lieu of something more attractive or as an easy means of making a living. At the present season, when all our medical colleges are beginning their courses of winter lectures, many young men are preparing to matriculate as students of medicine for no better reasons than those just referred to.

We wish that those who were about to take up this profession as a life work would seriously peruse an excellent paper that was published in the *Forum* last February, by Dr. John S. Billings. He presents the practice of medicine as offering at this time opportunities for the employment of the highest mental faculties, for the increase of knowledge, for usefulness to the world, and for the attainment of true happiness such as no other profession carries with it. But he at once qualifies this attractive statement by saying that he does not mean to assert that it will certainly secure to its followers all these things, or indeed any of them, but that, given the same degree of intellect, with a good preliminary education, the probabilities are that, out of a thousand men taking up the study of medicine, more will attain success than will do so among the same number of young men of like attainments who devote themselves to the other liberal professions. He defines a successful career as one in which the individual has done the best work of which he was capable—work that is done interestedly, ungrudgingly, pleasurably, unselfishly, without the ulterior motive of acquiring wealth, or fame, or power thereby. He believes it “a career which has secured a happy home and sufficient means to support it, although it may not have led to wealth; it has brought to its pursuer the approval and friendship of those best acquainted with his life and work, although it may not have made him famous or given him decorations or formal honors; it has made his advice valued and sought for by those who know him, although it may not have given him an executive office or made him a ruler over his fellow-men. Such a career does not protect from the afflictions and sorrows common to humanity, but it does away in a great measure with boredom and ennui, with weary waiting for something to turn up, and the work itself is the best resource against inevitable grief.”

Dr. Billings then reviews some of the unknown regions of medicine, and considers the qualifications necessary to pursue it. He advises that the student should have taken his bachelor's degree at a large university, not merely to guarantee a proper training, but because of the atmosphere and associations there. He is then to take a four years' course of instruction in a medical school having ample hospital and laboratory facilities, and he is to serve for a year or more in a hospital. Following this should be several years of study in laboratories or in clinics where he may apply the knowledge he has acquired in his college training. Dr. Billings estimates that this plan will require an investment of some eight thousand dollars from the time the student entered the university. If the intending student has the means that will enable him to spend the time indicated, he had better so invest them; if he has not these means, he should carefully consider whether he had better not abandon all thought of studying medicine and try some of the numerous other occupations that offer a better investment for time and money, and wherein "he may be a less dangerous and more useful member of society."

Dr. Billings considers that there is no need in this country of men possessing the diploma of doctor of medicine, for it has at least twenty thousand more than it requires or can properly support; but that there is need of several hundred such properly trained physicians as he has indicated.

It is true that the successful practice of medicine demands either the highest qualifications, both moral and intellectual, or the most cunning and astute knavery. The latter does not, of course, lead to a true success, but it fills an extensive field, and that seems to afford great satisfaction to its patrons, with desirable rewards to its professors. The confidence-man in medicine finds a sphere for the exercise of his talents that is unsurpassed.

While we do not deny the accuracy, in part, of Dr. Billings's definition of a successful career, it is manifest that it ill accords with the common acceptance of what constitutes such a career. A man may do all these things and be a hod-carrier, and yet he could hardly be considered as attaining a successful career. And there are mental hod-carriers, men that never get beyond "hack" work all their lives, who would still be examples of all the virtues catalogued as essential to a successful career.

It has been said that the public is not a good paymaster of the medical profession; it is less than that, it is not a good partisan of the medical profession. William Cobbett, perhaps smarting from Benjamin Rush's vengeance, once wrote: "The respect due to the profession of the surgeon or physician is, however, of an order inferior to that which is due to the profession of the law; for the character of counsellor or of judge . . . has, in the affairs of men and on their condition in life, a much more extensive and more powerful influence than can possibly arise from the application of surgical or medical knowledge." This opinion is still prevalent, and we know of no profession in which there are more instances of "the spurns that patient merit of the unworthy takes," and this unjust con-

temning is not confined to the illiterate or half-educated. Every physician that reads these lines must have knowledge of this fact.

The good physician, like the poet, is born, not made. There is one great prototype that is acknowledged throughout Christendom as his Exemplar. To an expensive investment of time and money necessary to acquire his education, as Dr. Billings has shown, the neophyte must add an instinctive love for such a vocation, as well as a willingness to strive for ideals more comprehensive than those set forth by Dr. Billings, because there must be a determination to ignore insult, injustice, and ingratitude and to exhibit courage in face of the adversity attendant upon building up a practice. Of such a physician it must always be said:

And thus he bore, sans bate or ban,
The grand old name of gentleman.

MINOR PARAGRAPHS.

HASHEESH-SMOKING IN EGYPT.

DR. MACKENZIE, of Cairo, states in the *Chemist and Druggist* for July 29th that the use of Indian hemp prevails to a considerable extent in lower Egypt, although both the importation of the drug and the cultivation of the plant are forbidden by law. The plant is grown clandestinely to a small extent. The smuggling of the prepared hasheesh is carried on quite extensively, chiefly by Greek traders and seamen. Hasheesh as bought from a shop (and that is easily done) is an earthy-brown substance in lumps, which may be easily broken. It is prepared by taking the small leaves and female flowers from the tops of *Cannabis indica*, rubbing them down to a powder, putting through a fine sieve, and heating the dark-green powder thus obtained till it becomes cohesive, and then working up into lumps by the hand. It is smoked in a special pipe called a *goza*, having a bulb for water and two tubes, one for the mouth and the other for the bowl. The bowl is first charged with tobacco, then with a small piece of the hasheesh; upon this is placed a live charcoal. The odor of the burning hasheesh is peculiar—unlike any other known to the writer. Of the effects of the inhalation of the burning drug Dr. Mackenzie thus writes: "It first produces that exhilaration which leads on to those deeds of violence that have gained for it its evil reputation; this is followed by a dreamy condition similar to that enjoyed by opium smokers, and, no doubt, constituting the charm which tempts the *hashash* (as the hasheesh smoker is called) to a miserable future. Insanity is a frequent result of the too free indulgence in this species of intoxication, and there are many to be seen who, having been well educated and having filled important posts, have fallen victims to the drug." The seeds of *Cannabis indica* differ from those of common hemp (*Cannabis sativa*) in having a tougher coat, which difference may be distinctly observed by taking the seeds between the teeth and crushing them. The hasheesh seeds are also more flattened and sharper at the edge when cut through the middle; the section thus seen shows a dark line between the husk and the albumen, while in common hemp seeds this dark substance is not so conspicuous or is absent altogether. The active principle of hasheesh is generally supposed to be a resin, which was first obtained by T. and H. Smith; other investigators have isolated a volatile oil named cannabene (Personne) and an alkaloid, tetano-cannabine (Hay). Nicotine is said to

have been obtained, but that has since been denied, and some authorities say the active principle has not yet been isolated.

REINDEER MEAT AS FOOD.

A CLERGYMAN, the Rev. Mr. Wallis, who has lived for several years on the Porcupine River, in the British northerly possessions, writes entertainingly of his manner of life in that frigid region. "Many times," he says, "I have subsisted almost exclusively on reindeer meat. It is very good, and I may say it is about the only kind of meat you don't get tired of. I think it is better, all things considered, than beef, and that you can eat it longer without its palling on you. It is a venison more than anything else. The Indians eat it almost exclusively, and they are very big and strong. Some of them are six feet in height and the average is about five feet ten inches. They are genuine North American Indians, and not the Aleuts, Eskimos, or a mixture of the two. I keep an Indian hunter and he supplies me with all the reindeer meat I want. He also brings me in grouse, ducks, bear, and other game as I need it. I have learned to shoot pretty well myself, as the white men do in that region or anywhere contiguous to it. The ducks and grouse, like the reindeer, are remarkably good eating."

THE DOCTOR AND THE JANITOR.

THE newspapers lately gave an account of an incident that shows one of the attractive features of apartment houses. It seems that two sisters were living together in a "flat," and that during the night one of them went out to get a physician to visit the other, who was sick. When the lady got back to the house, accompanied by the doctor, she was accosted by "the lordly janitor," as the *Sun* calls him, and told that that was a respectable house, and she could not bring a strange man into it at night! And then, the account goes on to say, the janitor actually ejected the physician.

A COLONY OF MERCY.

A SMALL book with this title has been issued in London. The author's object is to describe the beneficent work of Pastor von Bodelschwing at Bethel, Westphalia. The reverend gentleman is well known in this country for the labor colony he has originated for the benefit of epileptics. The pastor comes from a noble family. He was a schoolmate of the late Emperor Frederick and his father had been a cabinet minister of Prussia. He was partially educated for official position, but his mother's influence directed the current of his thoughts toward practical philanthropy and missionary work. For a time he labored among the rag-pickers and crossing-sweepers of Paris. The ill-health of his wife led him to return to Germany, and not long afterward he was placed in charge of a small hospital for epileptics at Bielefeld, a manufacturing town of his native province. This was about twenty-five years ago. He began by caring for twenty-six male epileptics; he now superintends a thousand or more inmates in sixty cottages, on a farm of four hundred acres. It is not generally known how great is the diversity of employments brought within the scope of the farm colony. For example, it is stated that a large trade is done, with many and distant places, in providing a pure bromide of potassium, which is about the only drug that they use for the epileptic patients. There has also been established at Bethel a labor colony for reform-seeking inebriates. They are admitted under a pledge to undergo treatment for a year, or longer if so directed. All wages are forfeited by those inmates who break through their pledge of abstinence. This subcolony is called "Friedrichs-Hütte." Those who seek the advantages of this

retreat are required to do their share of the honest daily toil which is, in part at least, the curative agent that is the pastor's chief reliance.

THE WESTCHESTER FREE HOSPITAL.

THIS institution was opened about September 1st. Many persons visit it daily and not a few leave substantial donations. The following is the medical board for 1893:

Consulting Physicians—Dr. Clement Cleveland, gynecologist, New York; Dr. J. E. Ellis, Westchester; Dr. Frank W. Jackson and Dr. W. B. James, New York. Consulting Surgeons—Dr. Joseph B. Bissell and Dr. Arnold Naudain, New York, and Dr. Z. E. Lewis, New Rochelle. Out-patient Department—Dr. W. C. Deming, attending physician and surgeon, and Dr. W. B. MacNichol, Westchester, and Dr. Frank Anson Becker, West Farms. Pathologist, Dr. J. S. Thacher, New York.

A POST-OFFICE RULING REGARDING DISEASE GERMS.

THE *Boston Medical and Surgical Journal* for August 24th states that the Postmaster General has made a ruling that disease germs are to be classed with unmailable articles, no matter how securely they may be sealed.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 12, 1893:

DISEASES.	Week ending Sept. 5.		Week ending Sept. 12.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	0	0
Typhoid fever.....	19	7	37	11
Scarlet fever.....	23	2	31	1
Cerebro-spinal meningitis.....	74	0	6	5
Measles.....	50	2	57	7
Diphtheria.....	3	2	95	28
Small-pox.....	7	0	8	2

The American Orthopedic Association.—The seventh annual meeting will be held in St. Louis on Tuesday, Wednesday, and Thursday, the 19th, 20th, and 21st inst., in the lower hall of the College of Pharmacy, 2110 Lucas Place, under the presidency of Dr. A. J. Steele, of St. Louis, besides whose presidential address, entitled *The Embodiment of an Idea*, the programme includes the following:

Tuberculosis and the Mind Cure, by Dr. Ansel G. Cook, of Hartford; A Case of Fragilitas Ossium, exhibiting over One Hundred Broken Bones, by Dr. Wallace Blanchard, of Chicago; Congenital Deformities, by Dr. De Forest Willard, of Philadelphia; A Case of Deformity of the Lower Limbs with Spina Bifida, by Dr. W. J. Taylor, of Philadelphia; Congenital Absence of Both Clavicles, with Rotaro-lateral Curvature—Specimen; and A Case of Congenital Dislocation of the Hips—Patient, by Dr. A. J. Steele, of St. Louis; Some of the Uses of Continued Extension, by Dr. Henry G. Davis, of Everett; Historical Notes of the Use of Traction in Diseases of the Joints, by Dr. A. B. Judson, of New York; The Value of Traction in the Treatment of Joint Disease, by Dr. H. L. Taylor, of New York; The Value of Traction in Hip Disease as Investigated by Experiment, by Dr. E. H. Bradford, of Boston; Exhibition of New Traction Mechanism for Hip Splints, with Remarks, by Dr. L. A. Weigel, of Rochester; A Modification of the Long Traction Splint for Hip Disease, designed to provide a Light Apparatus for Little Children, by Dr. Augustus Thorndike, of Boston; The Question of Excision of the Hip Joint for Tubercular Disease, and the Results of the Operation, by Dr. Harry M. Sherman, of San Francisco; Cases of Osteo-sarcoma simulating Tubercular Hip-joint Disease, by Dr. A. J. Gillette, of St. Paul; Acute Epiphysitis, by Dr. E. G. Brackett, of Boston; High Temperature in Chronic Joint Disease, by Dr. R. W. Lovett,

of Boston; The Treatment of Abscesses and Sinuses, by Dr. A. M. Phelps, of New York; The Treatment of Abscesses caused by Diseased Joints, by Dr. H. G. Davis, of Everett; The Etiology of the Deformities of Knee-joint Disease, by Dr. A. M. Phelps, of New York; The History of the Treatment of Tumor Albus of the Knee, by Dr. J. D. Griffith, of Kansas City; A Contribution to the Treatment of White Swelling of the Knee, by Dr. A. B. Judson, of New York; The Value of Fixation in Knee Disease, by Dr. G. W. Ryan, of Cincinnati; The Value of Traction in Tumor Albus of the Knee, by Dr. E. H. Bradford, of Boston; A Splint for making Traction in the Line of Deformity in Knee-joint Disease, by Dr. R. W. Lovett, of Boston; Exhibition of the Ideal Knee Splint, with Remarks, by Dr. John Ridlon, of Chicago; Exhibition of a New Knee Splint, its Action and Advantages, by Dr. A. E. Hoadley, of Chicago; The Operative Treatment of Knee-joint Disease, by Dr. De Forest Willard, of Philadelphia; Excision of the Knee in Young Adults, a Study of Twenty-nine Cases, by Dr. C. L. Scudder, of Boston; The Advantages of the Gradual Reduction of Flexion of the Knee due to Tumor Albus, by Dr. Augustus Thorndike, of Boston; Forcible Correction of the Deformities resulting from Knee-joint Disease, by Dr. J. E. Goldthwait, of Boston; Internal Derangement of the Knee Joint, by Dr. L. A. Weigel, of Rochester; The Mechanical Treatment of Osteo-arthritis of the Knee, by Dr. H. L. Taylor, of New York; The Treatment of Injuries in and about the Knee by Massage, by Dr. Benjamin Lee, of Philadelphia; The Mechanical Treatment of Light Cases of Knock-knee, by Dr. Florian Beely, of Berlin; The Manual Treatment of Bow-legs and Knock-knee, by Dr. Samuel Ketch, of New York; Observations upon the Etiology and Treatment of Scoliosis, by Dr. A. E. Hoadley, of Chicago; The Treatment of Lateral Curvature by Pressure Correction and Gymnastics, with Lantern-slide Illustrations and Exhibition of the Paper Jacket, also of an Apparatus for recording Rotation in Lateral Curvature, by Dr. L. A. Weigel, of Rochester; Cast Correction in Connection with Jacket Construction, by Dr. Bernard Bartow, of Buffalo; Demonstration in the Making of Ideal Leather Splints, by Dr. A. J. Steele, of St. Louis; Observations on Pott's Disease, with Particular Reference to the Principles of Treatment and their Application, by Dr. Royal Whitman, of New York; The Cause of Flat Foot, by Dr. Newton M. Shaffer, of New York; A Double-lever Stretching Apparatus for Clubfoot, by Dr. T. Halsted Myers, of New York; Bone Operations for the Correction of Clubfoot, based upon an Analysis of Two Hundred and Ninety-three Operations by One Hundred Operators, by Dr. H. A. Wilson, of Philadelphia; A Case of Adult Clubfoot, by Dr. C. C. Foster, of Cambridge; A Case of Club-hand, with Result of Operation, by Dr. R. H. Sayre, of New York; Exhibition of a Splint-opener for Plaster-of-Paris Splints, also other Simple Devices, by Dr. Harry M. Sherman, of San Francisco; Exhibition of an Orthopedic Bed, by Dr. L. A. Weigel, of Rochester; and Exhibition of the Improved Stretcher Splint.

The Richmond Academy of Medicine and Surgery.—At the last meeting, on Tuesday evening, the 12th inst., a discussion on shock was opened by Dr. Edward McGuire.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 5 to September 9, 1893:*

HUNTINGTON, DAVID L., Major and Surgeon, is granted leave of absence for one month.

GREENLEAF, CHARLES R., Lieutenant Colonel and Deputy Surgeon General, is granted leave of absence for two months, to take effect from August 25, 1893.

A board of officers to consist of BAILY, JOSEPH C., Colonel and Assistant Surgeon General, DE WITT, CALVIN, Major and Surgeon, and CRONKHITE, HENRY M., Major and Surgeon, is appointed to meet at the call of the president thereof at San Antonio, Texas, for the examination of such officers as may be ordered before it, with a view of determining their fitness for promotion.

KILBOURNE, HENRY S., Captain and Assistant Surgeon, will report in person to Colonel Joseph C. Baily, Assistant Surgeon General, president of the examining board appointed to meet at San Antonio, Texas, for examination for promotion.

TAYLOR, MARCUS E., Captain and Assistant Surgeon, having been found by an army retiring board incapacitated for active service, is granted leave of absence until further orders on account of disability.

SMITH, ALLEN M., First Lieutenant and Assistant Surgeon, is granted leave of absence for four months, to take effect on or about October 25, 1893.

CABELL, JULIAN M., Captain and Assistant Surgeon, is relieved from duty at Fort D. A. Russell, Wyoming, and ordered to Washington Barracks, D. C., for duty with the company of instruction of the Hospital Corps.

Society Meetings for the Coming Week:

MONDAY, September 18th: Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, September 19th: Medical Societies of the Counties of Kings and Westchester, N. Y.; Ogdensburg Medical Association; Connecticut River Valley Medical Association (Bellows Falls, Vt.); Baltimore Academy of Medicine.

WEDNESDAY, September 20th: Northwestern Medical and Surgical Society of New York (private); Harlem Medical Association of the City of New York; Medico-legal Society; Medical Society of the County of Allegany, N. Y.; New Jersey Academy of Medicine (Newark).

THURSDAY, September 21st: Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement.

FRIDAY, September 22d: Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

Letters to the Editor.

MR. ERNEST HART AND THE AMERICAN MEDICAL PROFESSION.

WASHINGTON, September 12, 1893.

To the Editor of the New York Medical Journal:

SIR: The people of the United States are so accustomed to having their deficiencies in manners and customs pointed out to them by English mentors, who judge them by their own local standard, that those who heard Mr. Ernest Hart in his recent addresses at the Medical Editors' Banquet and before the Pan-American Medical Congress were not surprised at the advice and correction administered to the medical profession of this country. Standing on a pedestal of his own erection, with that apparent consciousness of rectitude which can brook nothing antagonistic, and forgetting that he was the guest of those who had paid for his entertainment and were therefore his hosts, he pointed out their faults, exposed their failings, laid down the principles by which they should be guided in their intercourse with each other and with the public, told them how good and pure their English brethren were, and with an air which seemed to say "Take me for your model of a medical man and a gentleman" sat down, doubtless with the feeling of having discharged a disagreeable duty in a highly becoming and especially modest manner.

To consider all Mr. Hart's objections to our manner of conducting ourselves, which, in his opinion, places us on a lower plane than that on which our English brethren stand, would take up more of your space than you would be willing to spare. I must therefore confine myself to two or three points which appeared to particularly excite his indignation, leaving it for others to take up some of the remaining alleged lapses from good manners and sound morals which, in Mr. Hart's opinion, some of us exhibit and all of us tolerate; for, whether or not

all do the things which Mr. Hart deprecates so strongly, so long as the guilty ones retain their fellowship in the societies to which they belong all are equally under the ban, and must accept for themselves the censure which their self-appointed guide awards them.

First of all, Mr. Hart objects to the portraits of medical men being published by the secular press. Now, Mr. Editor, the newspaper in this country prints anything that its editor thinks will interest its readers. When a Pan-Anglican, or Pan-Presbyterian, or Catholic Congress assembles in a city the portraits of its prominent members appear in the daily newspapers. When the Bar Association meets, the eminent lawyers' pictures are published the next day. When the Grand Army of the Republic, the Loyal Legion, or the Daughters of the American Revolution take possession of a city, the countenances of their leaders are the following morning exhibited to the public. Even the members of the Fat Men's Association do not escape this great honor. It would be something extraordinary if the doctors were passed over. The American public have a genuine affection and respect for the medical profession. It stands high among them, and is always referred to in the speeches of welcome given by governors, presidents, and mayors as first among all in the character of their labors for mankind, in their social standing in the community, and in the love of the people. No profession—not even the clerical—is capable of exercising one half the influence which is wielded by that to which we belong. The readers of newspapers (and every one here who can read reads a newspaper) wish to see the portraits of those who are prominent and of whom they have read and heard, and the editor prints them—not to advertise those whose features are presented, but to please his patrons.

Now, even in England the portraits of distinguished scientists, statesmen, soldiers, ecclesiastics, members of royal and noble families, etc., are continually appearing in the illustrated newspapers, but of medical men never until they are dead, when, if they have been specially eminent, and particularly if they have in the whole course of their lives attended a member of the royal family, their portraits with short biographies, in which this latter fact is given distinguished pre-eminence, are published in the *London Illustrated News*, the *Graphic*, and other papers of the kind. Why is this? We do not have to look far for the answer. It is to be found in the fact that the medical profession in England is of no social or political importance. The average medical man is a little lower than the lawyer, a little higher than the tradesman; the people do not care for him.

With us, on the contrary, no class ranks socially above the medical profession; in England its members are looked down upon with something of contempt by the nobility and gentry. When the question of raising a distinguished surgeon to the peerage was considered, an eminent member of the Government said, "No! I will never consent to make a peer of a man who will . . . for a guinea." [I leave the name of the surgical examination referred to by the eminent statesman to be guessed at by the intelligent reader. It can not be mentioned in your pages in the terms employed.] And there never yet has been a medical peer.

When an American physician pays a professional visit to the highest in the land, he goes in at the front door and waits in the drawing-room till summoned to his patient. In England the question was discussed in a medical journal a few years ago of whether, when called to the house of a nobleman or that of a country gentleman, the medical practitioner should go in by the main entrance or by that used by the servants. As a matter of fact, he often enters by the back door and waits in the hall until invited to go upstairs to his patient. Think of it, Mr. Editor!

Think of the members of a learned profession being treated as menials, and think of any one, from the President of the United States down, acting in such a way to his medical adviser! The social position of the average medical practitioner in England is one of extreme degradation, and no one knows it better than Mr. Hart. Here he calls upon the President of the United States and is treated with respect! At home the *entourage* of the Queen is closed to him.

Now, Mr. Hart, finding that medical men here are held in high esteem by the general public, that their portraits are printed, and that they are interviewed by reporters on subjects of interest, takes it for granted that they are seeking notoriety. They do not interview doctors in England, and hence they should not interview them here. He does not bear in mind the fact that in this country every one who has anything to say is interviewed, and the doctors are not overlooked.

I suppose, Mr. Editor, that we all like a certain amount of distinction and the good opinion of our fellow-men, and I am quite sure that Mr. Hart is no exception to this rule. But, really, before censuring us he should have looked a little more closely into his own conduct since he has been in "our midst." Probably his portrait has never been published in his own country, nor has he ever been interviewed. But when he had been with us a little while his likeness began to appear, not only in the medical but in the lay press, until to-day I doubt if the lineaments of any medical man in this country are so well known from Maine to California as those of Mr. Ernest Hart, and accompanied too by biographies so minute and specific that the details could only have been obtained from the subject himself.

And I submit that in the matter of a notoriety-seeking publicity no American physician would have gone so far as did Mr. Hart when he entered his name on the Arlington Hotel register in this city. I give the entry *verbatim et literatim*: "Ernest Hart F. R. C. S. D. C. L. London. Editor British Medical Journal. Dean of St. Mary's Hospital."

Mr. Hart has evidently tasted of the delights of freedom. He feels himself the equal if not the superior of any one, and, with that tendency of those who have suddenly been released from bondage to disport themselves hilariously, he has plunged into excesses which, to use his own expression, would cause him to be "tabooed in London." Think of Dr. Pepper, or Dr. Hughes, or Dr. Lavista of Mexico, stringing out his medical and collegiate qualifications, his editorial associations, and his hospital appointments on the pages of a hotel register! And yet the man who does this thing lectures us on our medical manners and patronizingly tells us how we should live in order to merit the commendation of his countrymen.

Another crime which Mr. Hart accuses us of committing is talking to the public about our patients and revealing the secrets of the sick-room. He declared that we did this with "the ballet dancer, the prize fighter, and the President of the United States." I pass over the execrable taste displayed in associating the head of the nation with a ballet dancer and a prize fighter. I have only to say that when Mr. Hart made the accusation to the effect that American medical men were more guilty of these crimes than their fellows of any other nation in the civilized world, he said what was not true. In all countries the health of prominent persons in any position of life is a matter of public interest. This is just as true of England as it is of this country; for when a member of the royal family or other distinguished person is ill, bulletins are issued regularly by the physicians in attendance, so that the public is kept fully advised of the condition of the patient. In the United States, if this is sometimes done by interviewing the medical attendants, with the consent of the patient, it is only because we accomplish in

one way what in England, where they do not have the interview, they bring about in a different manner. Mr. Hart, taking English customs for his guide, finds fault with us because we do things in a different way from that to which he has been accustomed. In this he displays that insular narrow-mindedness which is so characteristic of the middle class of his countrymen. We cut loose from England more than a hundred years ago, and we regulate this and other matters for ourselves, just as they are governed by their own customs in France, Germany, and other European countries. As to our abusing professional confidence, it is an act almost unheard of among American physicians. So sacred do we regard the relations that exist between physician and patient, that many States have passed laws (the like of which do not appear on the English statute books) protecting the physician from being questioned as a witness on any point of knowledge acquired by him as a medical attendant.

Relative to Mr. Hart's opinions, which he freely expressed, in regard to physicians having a pecuniary interest in the sale of any medical preparation, it is to be borne in mind that the "surgery" is the common appendage to the average English practitioner's residence, and that he there prepares and sells medicines, not only to his own patients, but to anybody who requires them, and that we see such items in the bills that he renders to his patrons (for he regards them as "patrons") as an "enema" so much, a "draught" so much, an "anodyne" so much, and so on. Besides, we must recollect that in this country many physicians dispense and sell their own medicines and that there is a strong impression existing in the profession that it would be well if this were more generally done.

But this is not all. Mr. Hart may reply that in these cases the physician does not own an interest in any of the medicines he sells, and that his remarks applied especially to those persons who did. Now, I happen to know a good deal about Mr. Hart's connection with an article which is used largely by physicians for their patients, which is extensively advertised in the medical journals, with certificates exhibited in regard to its virtue, and which I and other physicians, at Mr. Hart's request, were mainly instrumental in introducing into this country. This article is the Apollinaris water, and Mr. Hart is or was at that time a large stockholder in the company owning the spring. A case of the Apollinaris water was sent to each of us (I refrain from mentioning the names of the others, but you will doubtless recall the circumstance), and we were requested to use it and to give our opinions of it for publication in the daily press. At that time many members of the medical profession thought it a violation of the code of ethics to give certificates of the kind. We were notified by the president of the Medical Society of the County of New York, Dr. John C. Peters, that we ought to withdraw them, and this was done after they had been published a few times. So that the only occasion on which the authorities of any medical society to which I belong have considered themselves obliged to call my attention to an alleged violation of the code of ethics was brought about by Mr. Ernest Hart in his desire to extend the sale among physicians and the public of a medicinal article in which he was pecuniarily interested!

I have not yet covered all the ground that I had intended to occupy, but there are other members of the Pan-American Medical Congress from whom you and other editors of medical journals will doubtless hear, and I therefore leave Mr. Ernest Hart at present for their consideration. I will only say that, if any American physician had made in England such speeches as Mr. Hart made on the two occasions referred to, he would have been coughed down or hissed into his seat with a degree of brutality which educated Americans never exhibit.

WILLIAM A. HAMMOND, M. D.

Proceedings of Societies.

FIRST PAN-AMERICAN MEDICAL CONGRESS.

Held in Washington on Tuesday, Wednesday, Thursday, and Friday, September 5, 6, 7, and 8, 1893.

(Continued from page 302.)

SECTION IN GENERAL SURGERY.

The Address in Surgery.—Dr. JOHN B. HAMILTON, of Chicago, who presided over the Section in General Surgery, after some gracefully turned expressions of welcome to the strangers, said that the rapid evolution of surgical knowledge was one of the wonders of this remarkable age, and surgeons might well proclaim that their own branch of medicine had kept equal pace with the stupendous advances made by the collateral sciences. A review of the surgical progress of the last decade alone constituted one of the most brilliant pages of the history of medicine. Still, it must be remembered that all scientific progress was based on antecedent fundamental facts discovered by slow, laborious, and often painful steps. The labors of Darwin, Huxley, Herbert Spencer, Pasteur, and Lister in the last decade had made possible the practical successes in the present one. At this time no diseased organ or tissue of the body escaped the remedial scalpel, and an examination of the discussions going on at this time showed that the questions presented were rather those of method than of original discovery. We now no longer questioned the propriety of surgical interference in previously dark portions of the human anatomy, and were concerning ourselves principally with the technique of that interference. The subject of surgical bacteriology, which included the chemical study of microbic products, had yet much to disclose; still, we already based our practice on an immortal discovery by Pasteur. The success of modern surgery was such that even with the imperfect knowledge of the bacteria now possessed no surgeon thought for a moment of comparing the results of any given operation of to-day with those obtained in the pre-microbic period. Bacteriology had added much to our knowledge of tuberculosis and had given some precision to its treatment, though this was still far from satisfactory. The carcinomata still remained one of the mysteries of medicine. We had for years studied the varying departures of the tissues from the normal to the abnormal, and the bacteriologist had in vain sought to connect the atypical structure of carcinoma with some bacterial development, but no Pasteur or Harvey had yet dawned upon the horizon to solve this mystery, to which Heaven had apparently left this generation no key. No doubt the solution of the formation of carcinoma would yet be discovered, and the study of embryology and atavism seemed at present the most probable avenues to that end. As to the future of surgery, it was likely that the questions relating to improvements in technique would occupy the surgical mind until some epoch-making discovery was reached. Some help might be expected from the collateral sciences. Transillumination of the body might yet be fully developed in our time. Instruments of precision and aids to hearing and vision would greatly assist in making our present knowledge useful. The great outlets to human life, like carcinoma, would in all probability have their genesis understood by surgeons yet unborn.

Some Defects in Anatomical Teaching in the Medical Schools of the United States.—Dr. JOHN B. ROBERTS, of Philadelphia, read a paper on this subject. He said that it was

impossible to appreciate the confused ideas of human anatomy obtained by a first-year pupil who knew but little physics, less biology, and no Latin. Such a pupil had no conception of the meaning of the descriptive Latin names of anatomical structures, yet he listened to lectures full of scientific terms and was expected to dissect the human body. To call such indecent butchery dissection was a farcical misnomer, as every demonstrator of anatomy knew. It would be much better to let such ill-trained hands learn the difference between muscle and fascia, nerve and vessel—which was about all such bungling taught these students—upon the dead bodies of the lower animals, and postpone the dissection of the human cadaver until the second or third year of the course. If it was true that much of the unsuccessful anatomical teaching was due to the poor quality of the recipients, it was none the less demonstrable that a more extended influence for evil was exerted by the inferior qualifications of teachers and the unscientific methods of teaching permitted in some schools. This was to a certain extent the result of a custom that permitted a professor once appointed to hold his position without forcible criticism until he died or resigned. The occupant of a professorial chair was practically an autocrat by courtesy. No criticism was too severe, the author said, for the system which placed first-course and second-course medical students in one class-room to hear the same didactic lectures on anatomy. Such a parody of instruction was probably unknown except in medical schools. Experience with students had abundantly shown the author that in certain things it would not be unwise to return to methods employed for teaching in the middle ages. Nude models grouped for lectures, representing the effects of disease on anatomical landmarks, were most valuable and essential in sustaining interest in clinical anatomy. He would urge that a thorough preparatory course be given to medical students in biology and in such lines of work as would better fit them for the direct work upon the human cadaver, and, all other things being equal, in this way only could we ever expect to produce thoroughly competent surgeons. While the speaker handled without gloves the present well-known glaring inconsistencies in this branch of medical teaching, he did full justice to those schools which were raising the general standard of teaching.

A Brief Splint Technology for Surgeons.—Dr. E. A. TRACEY, of Boston, read a paper with this title. He said that the object of his short treatise was to set forth in detail the particular merits of a new material suitable for use in surgical splint-making, to urge the surgeon to become the maker of suitable splints for cases occurring in practice, and to indicate lines of procedure in apparatus-making which promised rich results in general and orthopedic surgery. The basis of the material employed was wood pulp, made preferably from the crushed fiber of the poplar tree. This was rolled into sheets in such wise that the fibers intertwined in every direction and loosely, thus giving an increased ductility to the product. These sheets were further strengthened by having a fabric introduced between the layers of the pulp, or by interweaving with the short, crushed wood fibers a long jute or other tough fiber. The sheets were made of several thicknesses; for convenience they were designated by number—each figure representing one millimetre. Thus, sheet 1 had a thickness of one millimetre, sheet 2 of two millimetres, and so on. The characteristics of this material were stiffness or rigidity when dry, and plasticity with toughness when moist. Its rigidity could be increased *ad libitum* by the use of a silicate solution as a moistener. Water, or a stiffening solution, could be used to moisten the material previous to molding. The advantage of water was its omnipresence. With its aid a serviceable splint could be made.

Such a splint, however, was liable to be softened by the absorption of perspiration, or, on children, of urine; and for this reason it should be protected by a covering of oiled paper or silk, or mackintosh, or, best of all, by a coat of varnish. A solution of potassium silicate had several qualities which rendered it the best of the stiffening solutions experimented with. Sodium silicate and a mixture of potassium and sodium silicates had nearly the same qualities. Any desired degree of rigidity up to brittleness could be given the splint by using a silicate solution as a moistener—the stronger the solution the more rigid the splint. A splint rendered rigid in this wise was not affected by perspiration, nor indeed by momentary contact with fluids, as in washing. Another quality, of exceptional advantage in cases of compound fractures, was that this solution had strong antiseptic properties. The manner of moistening the blank deserved mention. It was most satisfactorily done by applying, by means of a flat paste brush, the fluid used, on both sides, alternately, of the splint blank, and repeating until the proper amount of the fluid was absorbed. Practice enabled one to judge the precise amount of moisture suitable.

Dr. DONALD McLEAN, of Detroit, while approving in general terms of the construction of the splints as advocated by the author of the paper, said that there was one great fundamental principle with regard to the construction of splints which should never be lost sight of in practice and teaching, and this was the doctrine of simplicity. He had long believed that no man was fit to treat a fracture who could not improvise a splint, no matter where he was situated or what the nature of the fracture. He then described the method of applying what he termed his "newspaper splint." In applying this splint, say to a fracture of a long bone or after the resection of a joint, the speaker simply folded one or more newspapers to the desired thickness and then molded this to the limb, surrounding the paper with cotton and the whole with a roller bandage. He said both he and his pupils had now used this method for a long time and had found it eminently satisfactory.

Dr. REGINALD H. SAYRE, of New York, said he thought the material suggested by Dr. Tracey was very serviceable, but he would have liked to see it wetted, as he could then have judged of its adaptability for molding to the form without creasing.

The Relation of the Heart and Lungs to the Anterior Chest Wall as determined by Composite Photography.—This was the title of a paper by Dr. I. S. HAYNES, of New York (to be published).

SECTION IN GYNÆCOLOGY.

The Intra-uterine Tampon.—Dr. ANDREW F. CUBBER, of New York, read a paper with this title. He alluded to the fact that the vast experience in gynecology which had accumulated in the past fifteen years had educated us to accept measures which would have been regarded in preantiseptic days as inexcusably rash. The freedom with which the curette was now used within the uterus was an illustration in point. The usefulness of instruments for the dilatation of the uterus had been generally appreciated only during the era in question, and the same was true concerning the principle of drainage in its application to the uterus. Dilatation, curetting, and drainage were the three principal foundation stones upon which intra-uterine treatment might be said to rest. From the propriety of dilating the uterus to that of packing it with a tampon was a logical step. The vaginal tampon was an indirect and often unsatisfactory means of relieving uterine trouble. The intra-uterine tampon went directly to the source of the trouble, and had opened a new field in intra-uterine therapeutics. Sterilized gauze was the material which offered the greatest

number of advantages for such a tampon. In the gravid and puerperal uterus it might be used:

1. During the period of gestation. 2. During parturition. 3. Post partum, whether the labor occurred at term or prior to it. In the unimpregnated uterus its use was for:

1. Exploratory and operative purposes in connection with disease of the uterus and its appendages. 2. Hæmorrhage. 3. Endometritis. 4. Stenosis. 5. Accumulations within the Fallopian tubes.

In the gravid uterus the intra-uterine tampon might be used in place of the vaginal tampon to bring on uterine contractions and empty the organ, or occasionally to ward off an abortion. In placenta prævia it might be of signal service. With uncontrollable vomiting, the presence of a dead fœtus, or serious mechanical obstruction in the parturient canal, the tampon was preferable to bougies, bags, or tents, for the purpose of inducing an abortion. During parturition, if the first stage was protracted, the tampon might be used to assist dilatation. It was preferable for several reasons to the means which were in vogue. Post partum, the tampon was useful for hæmorrhage, as recommended by Dührssen, also for the hæmorrhage which followed abortion, and for sepsis after either abortion or labor at term, in connection with curetting and irrigation. If there was subinvolution the tampon was indicated also, for it stimulated the uterus to contraction and produced free depletion. In the unimpregnated uterus it was useful for dilatation in the presence of new growths, whether benign or malignant, especially if slow dilatation was desirable. If the appendages were to be removed for inflammatory disease, a precedent curetting and tamponing would be useful by producing free drainage and depletion. The tampon in these cases was a substitute for the uterine tent.

For the relief of hæmorrhage the direct pressure of the uterine tampon excelled the indirect pressure of the vaginal tampon. Especially was this true in profuse menstruation in women and young girls associated with anemia. The patient should be at rest in bed while the tampon was in place, and it might be necessary to give an anæsthetic while introducing it. With hypertrophy and inflammatory disease of the endometrium hæmorrhage might also occur, and the tampon would be useful in relieving it. In endometritis with suppuration, hypertrophy of the endometrium, or inertia of the uterine muscle and stasis of the venous circulation, dilatation with drainage by means of the tampon would prove very serviceable. Stenosis was believed to be an efficient cause of the prevention of egress of fluids contained within the uterine cavity. The belief was founded upon mature experience. Its treatment with dilatation and the tampon was recommended.

The usefulness of the tampon for the drainage of accumulations within the Fallopian tubes was believed to be of limited scope, depletion of the uterus, its cornua, and those portions of the tubes immediately contiguous being the area which it was most likely to reach. If the tubes were greatly displaced and if there were ovarian or circumtubal abscesses, little or no benefit would result from the use of the tampon. The tampon should always be used with caution, but it did not follow that it always required an anæsthetic or the same adjuncts which would be called for in a major surgical procedure. There were many cases in which it was safe and proper to use it in office and dispensary practice, especially if it was not to be inserted beyond the os internum. It should usually be preceded by curetting, irrigation, and sufficient dilatation to permit of easy introduction of the gauze strips of which it was composed. The decubitus of the patient at the time of its introduction was a matter of convenience for the operator. The tampon might be safely retained from a day to three days. It was better to

renew it frequently and secure gradual distention than to pack in too much material at the first sitting. It might be so modified as to quantify, firmness, and duration of retention that there were few if any cases in which intra-uterine treatment would be admissible in which it was contraindicated.

Dr. R. B. MACRY, of Memphis, recognized the fact stated by the reader that treatment with the tampon was an advance step in intra-uterine therapeutics; a few years ago such treatment would not have been generally recognized as legitimate or proper. Men would not have dared to use it. The treatment was especially valuable as forming a feature in the system of the antiseptic method. The speaker had been especially impressed with the importance of this means of treatment in obstetric practice and in cases in which the labor had proceeded to its termination normally. In some of these cases septic phenomena appeared on the third or fourth day after delivery and curetting of the endometrium revealed the presence of more or less decomposed material. This being removed and a tampon introduced, the septic phenomena would disappear and the patients get well, where otherwise the consequences would often be serious.

Dr. G. BETTON MASSEY, of Philadelphia, favored the use of the tampon in the gravid uterus and soon after delivery, but in the inflammatory condition of the unimpregnated uterus the tampon was likely to cause retention of the secretions and consequent harm, although it was possible that it sometimes had a counterirritant and alterative effect in such cases which might be beneficial. He believed that such cases would be more satisfactorily treated by the use of the galvanic current, one pole being introduced within the uterine cavity. As to the existence of accumulations within the uterus in young and unmarried women, he did not believe in them, and hence saw no indication for the tampon in such cases.

Dr. J. TABER JOHNSON, of Washington, believed that the field of usefulness of the intra-uterine tampon was very extensive, but his experience had not led him to use it so widely as had been advocated in the paper. Its use in post-partum hæmorrhage was certainly valuable, and he had saved life with it. There were cases of this character in which the patient could not be saved by the tampon, being hopeless whatever the method of treatment. As a means of drainage in cases in which there was pus in the Fallopian tubes, he was forced to admit that it was sometimes efficient, and then the dangers attendant upon an abdominal section were averted, but the number of cases of this character was not large. The suggestion of the intra-uterine tampon in labor cases in which dilatation was progressing slowly was a valuable one, and the substitution of this means for the vaginal tampon in such cases would be of great advantage both to the patient and to the physician.

Dr. E. W. CUSHING, of Boston, thought that such a paper as the one under discussion was valuable in tending to remove the fear which so many practitioners had of putting anything into the uterine cavity. In his own practice he had not used the tampon extensively, and he did not see the need of it in cases in which curetting and irrigation were required. If such measures were used, and with thoroughness, he believed that drainage would be as efficient as if the tampon were used in addition.

Dr. A. VANDERVEER, of Albany, was entirely in favor of the principles enunciated in the paper. He also wished to lay stress upon the fact that curetting should accompany the use of the tampon. The principle of draining the uterus was correct surgically, and should be universally recognized.

Dr. J. H. CARSTENS, of Detroit, believed that the intra-uterine tampon was only another of the surgical "fads" which were introduced from time to time. He would not deny its utility, however, in a limited number of conditions, especially

after miscarriage, and occasionally after labor at term. It was not a measure which could be recommended to the profession at large, the element of danger associated with it being too great. He believed that curetting and irrigation would accomplish all that could be done with the tampon. Even if the tampon acted efficiently, it could only drain away serum and pus; tissue *débris* could be efficiently removed by curetting and irrigation. In any case he did not believe that gauze would act as a drain.

Dr. CURRIER said that the principle involved in the tampon was one with which all practitioners, whether general or special, were brought in contact, and he believed that the measure advocated was sure to be useful to all in one form or another. The objection that the tampon shut in the secretions of the uterus was of course fatal if well founded, but the fundamental hypothesis with the speaker was that the tampon should be composed of material which was pervious and would drain. The principle of capillary attraction could not be denied. If, as was stated, only serum was drained away, that was an immeasurable advantage in cases in which the uterine vessels were turgid and congested. Curetting and irrigation might be sufficient for some cases, while in others the tampon would be of additional benefit. The use of the tampon was not a remedy for all uterine disease, but its field of usefulness was large and would probably increase as its effectiveness became more generally known.

The Treatment of Extra-uterine Pregnancy after the Viability of the Child.—Dr. J. TABER JOHNSON, of Washington, who read a paper with this title, believed that the question as to the proper treatment of ectopic gestation was no longer in doubt. All means which were not surgical were to be discarded entirely. There should be no trusting to chance in the presence of this condition, no matter what period had been reached when the diagnosis was made. The rights of the child in all such cases were insignificant compared with those of the mother. If viability had been reached, one should not wait until term or until the fetus died and decomposition took place. That meant exposure to and possible death from sepsis. If it were possible, the placenta should be removed with the fetus, but this was not always essential and often involved grave danger from hemorrhage. The question of technique, when the child was viable, was still undergoing evolution. There had been thirteen recorded cases in which living children had been removed, including two by Americans—Eastman and Lusk. The important points in such cases were to act rapidly and to avoid severe hemorrhage. Two cases were narrated in which the author had operated after viability had been reached, the first in the eighth, the second in the twelfth month of gestation. The first was fatal from difficulty connected with the placenta; the second was successful, the ovum being removed entire and with very little loss of blood.

Dr. JOSEPH PRICE, of Philadelphia, stated that an American, William Baynum, of Virginia, performed the first operation for ectopic gestation, in 1790, also a second one in 1799, and both women recovered. The speaker had operated in eighty-six cases of ectopic gestation, and was prepared to say that definite rules for universal application in such operations could not be laid down. To remove the entire gestation sac, in certain cases, would be sure and immediate death from hemorrhage, whatever the skill of the operator. It was in some cases many weeks before the attachments of the placenta could be safely loosened, and in the mean time the patient must run the gantlet of sepsis. Stitching the oval sac to the abdominal wall was not to be recommended. In some cases the placenta seemed to be attached to all the abdominal viscera. It was folly or worse to attempt to remove it. He reiterated the author's

statement that there was but one treatment for ectopic gestation, and that surgical, as soon as the condition was ascertained. The life of the mother only was to be considered. The children were almost invariably deformed and imperfect, and seldom lived more than a day or two. He deprecated the use of gauze according to the requirements of the case.

Dr. CARSTENS dwelt upon the fact that the fetus was sometimes not absorbed when it had been destroyed by electricity. He had seen two such cases. He approved of the surgical treatment as the only one which was proper.

The Technique of Cælio-panhysterectomy.—Dr. G. M. EDEBOHLS, of New York, read a paper with this title. The lithotomy posture was to be used, and the vagina thoroughly disinfected, also the uterine cavity, the latter being curetted and then irrigated with 1-to-2,000 sublimate solution. The vagina and uterine cavity were packed with sublimate gauze. The patient was then placed in the Trendelenburg posture and the abdomen opened by an incision large enough to permit of the extraction of the tumor. If the tubes and ovaries were healthy and the tumor did not exceed four kilogrammes in weight, the latter should be drawn out of the abdomen and two transverse incisions of the peritoneum made, one on the anterior, the other on the posterior aspect of the uterus, each incision extending from one broad ligament to the other. The flaps should be large enough to close the opening in the pelvic floor made by the removal of the tumor, the bladder and ureters being carefully avoided in dissecting the anterior flap. The uterine arteries were then tied, the ligatures being carried as far as, but not into, the vagina. The broad ligaments were then tied off by two additional catgut ligatures on either side, external to the tubes and ovaries. The ligatures were then cut short and the uterus with the tumor and appendages was removed in one mass. The peritoneal flaps were then brought together with a running Lambert catgut suture extending from the stump of one infundibulo-pelvic ligament to the other. The abdominal wound was then closed, the patient again placed in the lithotomy posture, the packing removed from the vagina, and another vaginal packing introduced for the drainage of the supravaginal fossa. If the ovaries or tubes contained any infectious material they were removed as soon as the abdomen had been opened. If the tumor extended above the umbilicus and weighed more than four kilogrammes, the cervix should be surrounded with an elastic ligature and the tumor above it cut away. The cervical canal should then be cauterized or disinfected with sublimate and the cervix itself be removed. If the pelvis was filled with multiple fibromata, or an intraligamentous growth, the different lobes should be enucleated one by one, and the process continued as already described. The advantages of this technique were: There was very little danger of infection from the uterus or vagina, the uterine arteries were securely ligated, very little blood was lost, the peritoneal cavity was securely closed, and no particular after-treatment was necessary.

Hysterectomy; Indications and Technique.—Dr. J. M. BALDY, of Philadelphia, did not propose to discuss in this paper the questions of ætiology or symptomatology. His conclusions were drawn from the seventy-seven hysterectomies which had been performed by him. The indications for the operation were absolute and relative, and included malignant degenerations, fibroid tumors, pelvic inflammations, prolapsus uteri, and inversio uteri. For malignant degenerations the indication was absolute, the operation was always justifiable, even though relief was obtained for only a short period. Operations should be done as early in the history of the disease as possible, and the results would improve as one's experience and dexterity increased.

For fibroid tumors the indication was relative. If the tumor was small and not troublesome, and if the patient was approaching the menopause, the operation would seldom be required. Myomectomy was indicated only in cases in which the possibility of subsequent pregnancy was believed to be decided. The results of hysterectomy for fibroid tumors would be good if the cases were judiciously selected. For pelvic inflammation the indication was relative. The operation was sometimes required in cases in which relief had not been obtained by the removal of the tubes and ovaries, the uterus still remaining large and exhausting discharges continuing.

For prolapse of the uterus the indication was absolute. The question of a possible subsequent pregnancy was not to be considered in such cases. Plastic operations for such a condition were often far from satisfactory. Malignant disease was likely to ensue if such cases were not treated radically. In addition to the hysterectomy, plastic operations might also be performed.

For inversion of the uterus the indication was absolute. A combined abdominal and vaginal operation was recommended. Ligatures or clamps could be used to secure the broad ligaments, but the former were preferable. Supravaginal hysterectomy was advised for all conditions except malignant disease. The technique employed by the speaker was given in detail.

Dr. H. J. BOLDT, of New York, stated that the prognosis in hysterectomy would vary according as the supravaginal operation or complete extirpation was practiced. The result would also depend upon the size and attachments of the tumor. The speaker indorsed the technique recommended by Dr. Edebohl, with the modification that if the tumor was firmly fixed in the pelvis it was better to release its lower attachments by the vagina. In women who were very anæmic supravaginal amputation was preferable, as it involved less shock and could be accomplished in the shortest possible time. If the tumor extended into the broad ligament, no fixed rules for operation could be given; each case must be treated according to the conditions involved.

Dr. J. H. CARSTENS, of Detroit, preferred the use of the serre-nœud to ligatures in hysterectomy, the stump being secured to the abdominal wound.

Dr. C. P. NOBLE, of Philadelphia, thought the technique recommended by Dr. Edebohl perfect, but it applied only to tumors which were not massive and which were easily removed. For the more difficult cases he preferred the use of the serre-nœud with amputation at the level of the os internum, the stump being covered with peritonæum. The removal of the appendages alone would be the operation of choice with him for many cases of fibroid tumor.

Dr. I. S. STONE, of Washington, favored the operation recommended and practiced by Dr. Baer and Dr. Goffe, the ovaries and tubes being always removed with the uterus. The Trendelenburg posture was of great assistance in these operations if the tumor was movable. If the uterus and tumor were rigid, he was in the habit of using a large sound or staff with a cup-shaped attachment (which was exhibited), by which the mass could be lifted up in the pelvis, this serving as a guide in cutting away the uterus.

Dr. A. F. CURRIER, of New York, had practiced the method recommended by Dr. Edebohl with satisfactory results. It involved the minimum of shock to the patient and, according to his experience and belief, offered the most favorable conditions for complete and rapid recovery. If the patient was so reduced that a prolonged operation would be especially hazardous, the Hegar operation was to be preferred, and it often resulted in complete cure.

Dr. H. O. MARCY, of Boston, called attention to the method of enucleation of pelvic tumors recommended years ago by Miner, of Buffalo, also to his own work and recommendations in this field which he had first advocated in 1880. He always preferred to leave the cervix uteri if possible, as it was a means of strength and security to the pelvic floor.

Dr. E. E. MONTGOMERY, of Philadelphia, objected theoretically to the extraperitoneal method, but it was demanded in some cases, especially those in which rapidity of operation was essential. For the smaller tumors the method described by Dr. Edebohl was excellent. For inflammatory conditions of the uterus in which only a portion of the organ was involved he preferred to remove the diseased portion and leave the remainder.

Dr. L. S. McMURTRY, of Louisville, said the discussion was an evidence of the progress which had been going on in the consideration of the subject at issue. Fibroid tumors were no longer considered harmless or insignificant. The form of operation which one would choose was largely the result of training and experience, but one should not be prejudiced in favor of any particular operation to such an extent as to prevent his seeing and profiting by the favorable features of other methods. Hysterectomy would always be a serious and difficult operation whatever method was followed, and there were some cases of fibroid tumor which were entirely inoperable if the safety of the patient was considered.

Dr. J. TABER JOHNSON, of Washington, advocated the Hegar operation for many of the cases of fibroid tumor. In twenty-two cases in which he had operated bleeding had been permanently checked in every case but one.

Dr. EDEBOHL objected to the recommendation of releasing the attachments of a fibroid tumor by vaginal incision in combination with the abdominal method. The time consumed in operations of the character described would depend upon the skill of the operator.

Dr. BALDY stated that he had reached his conclusions after a trial of all methods, and so justified his statement that those he recommended were the best. The vital questions at issue were those of sepsis, shock, hemorrhage, and the time consumed. All conditions were, in his judgment, met most favorably by the extraperitoneal method.

A Plea for the Early Diagnosis and Prompt Electrical Treatment of Fibroid Tumors of the Uterus was the subject of a paper by Dr. G. BETTON MASSEY, of Philadelphia. The ætiology of the fibroid condition, or fibrosis, was obscure. The process was allied to inflammation; it was a perversion of the nutritive supply, an affection of a local trophic process. It simulated metritis, especially the chronic form. A fibroid of the uterus was almost like a foreign body in the pelvis; hence it excited symptoms in its early stages and should receive appropriate early treatment. Ovarian disease was often immediately dependent upon such a process. The existence of this condition was sometimes revealed at a very early period by the use of electricity, and might be cured at an early stage by such means. But in many cases the disease could not be thus made out, and the process was far advanced before it was discovered. It was not always essential that strong currents of electricity should be used in treating this condition. The author had treated many cases for periods ranging from a year to six years. He believed that all the patients had been benefited and some had been cured. If a tumor had existed a long time, especially if it had become cystic or had suffered inflammatory changes, electricity was not indicated.

The Results of Vaginal Hysterectomy.—This subject was discussed by Dr. A. J. MCCOSK, of New York, who gave a record of his personal experience. He believed that four years

should elapse after an operation for cancer before a patient could be considered cured. Even after such an interval recurrence might take place, though rarely. If infiltration into the broad ligaments had occurred, radical treatment was out of the question, as a rule. If the uterus was twice as large as the normal unimpregnated organ, the vaginal operation was impracticable. There could be no fixed plan for the treatment of all cases. To secure the broad ligaments, the author preferred ligatures to clamps, but the latter were sometimes required in emergencies. Fine silk was preferred to catgut as a ligature material. If the disease was very extensive, a high cervical amputation and cauterization were indicated, but only as a palliative. The sacral operation was not favored. For prolapse of the uterus, plastic operations would usually suffice, but exceptionally hysterectomy was indicated. Even if hysterectomy was performed, the vagina would usually protrude again in from three to six months unless plastic operations were also performed. If prolapse recurred, an abdominal section might be made and the vagina be drawn upward and attached to the abdominal parietes. The hæmorrhage from the vagina was often troublesome when the uterus was removed for prolapse.

Cavernous Angelioma of the Uterus removed by Vaginal Hysterectomy.—The case was reported by Dr. H. J. BOLDT, of New York, and the specimen was unique. The condition was to be distinguished from cavernous myoma, which was not of uncommon occurrence. The uterus had been removed on account of obstinate hæmorrhage, which was not relieved by repeated curetting.

Vaginal Hysterectomy.—A paper on this subject was read by Dr. E. E. MONTGOMERY, of Philadelphia. Complete extirpation of the uterus for cancer always held out better prospects of permanent cure than an incomplete operation. If the disease was limited to the uterus, the fact being determined by its mobility and the absence of induration in the contiguous tissues, there should be no question as to the propriety of an operation. The author did not favor the operation for inflammatory conditions of the pelvis, as recommended by Péan and Segond. It was sometimes warrantable for myoma of the uterus, if the tumor was small but very troublesome. The symptoms which indicated cancer of the uterus were pain, hæmorrhage, and a watery offensive discharge from the uterus. The speaker favored the use of clamps for securing the broad ligaments; they were easy to apply, and usually their use was not accompanied with hæmorrhage, but they might give rise to pain. The danger of wounding the bladder and ureters must always be considered. The author had operated twenty-one times for cancer, and all the patients but one had recovered.

Dr. HOWARD KELLY, of Baltimore, urged the importance of seeing cases of cancer of the uterus before the disease had become extensive. Women should be examined with reference to this condition at stated intervals after confinement, at least as often as once a year. He was convinced that the disease usually developed in cervixes which had been badly torn during labor. Curetting and cauterization would often be very helpful in the advanced cases. The speaker's method of operating was described in detail.

Dr. O. P. NOBLE, of Philadelphia, thought vaginal hysterectomy was very rarely indicated for prolapsus; plastic operations were usually efficient in his experience.

Dr. G. M. ENEBOHLS, of New York, believed that vaginal hysterectomy was indicated for prolapse only when there was a suspicion of a developing neoplasm, or the uterus was so large that complete reduction was not easy. If extirpation was performed, plastic operations should be done at the same time.

Dr. BALDY expressed his decided objection to the use of clamps in hysterectomy. He had lost two patients from hæmor-

rhage on whom clamps had been used. If the broad ligaments were stitched to the vagina after the uterus had been removed for prolapse, a recurrence of the prolapse would not take place.

Dr. McCOSKIR expressed his preference for silk rather than catgut as a suture material, as it was more easily made aseptic.

Dr. MONTGOMERY stated that he preferred clamps in hysterectomy on account of the saving in time which resulted. The Greig Smith clamp would never slip.

The Present Status of our Knowledge of the Pathology of Pelvic Inflammation, with Special Reference to the Anatomy and Treatment of Pelvic Abscess.—Dr. R. B. MAURY, of Memphis, Tenn., read a paper upon this subject. He defined pelvic abscess as any collection of pus within the pelvis, no matter what its anatomical relations might be. The definitions of pelvic inflammation, as stated by Thomas and Emmet in their works on gynecology, were compared with the views which now obtained. Pelvic cellulitis was now known to be an acute inflammation which might accompany puerperal septicæmia or occur as the result of surgical procedures upon the uterus or vagina. It was also known that it seldom occurred, even in the puerperal state, at least to such a degree that the exudation was appreciable to the examining finger. Death resulting from septic conditions following surgical operations upon the pelvic organs usually signified peritonitis, not cellulitis. But pelvic cellulitis of moderate intensity and extent was frequently associated with pelvic peritonitis, the former not being recognizable at the bedside. The existence of such a condition as chronic pelvic cellulitis was doubtful, and its clinical recognition quite impossible. The great importance of pelvic peritonitis associated with disease of the uterine appendages had been clearly pointed out by Bernutz. The purulent collections which were to be considered by the author were those which resulted from inflammation of the pelvic cellular tissue, salpingitis, oophoritis, and pelvic peritonitis. Abscesses in the broad-ligament cellular spaces were rare, and their anatomical relations were not usually reported with sufficient accuracy. The great majority of pelvic abscesses were intraperitoneal. During the prevalence of the old ideas concerning pelvic cellulitis such abscesses were attacked through the vagina or by an incision extending to the cellular tissue in the abdominal wall. In exceptional cases such treatment might still be entirely proper, especially for the extraperitoneal abscesses. For those which were intraperitoneal the proper method of treatment was by abdominal section, with removal of the abscess sac. The Péan-Segond method of removing the uterus *per vaginam* in treating such abscesses merited entire disapproval.

Dr. W. G. BERNAYS, of St. Louis, wished to correct a misapprehension which probably existed in the minds of the reader of the paper and of others concerning the Péan-Segond operation. The plan of the operation was not to remove the entire uterus, but only such a portion of it as would enable the surgeon to reach the pelvic abscess with his finger or an appropriate instrument. He had done the operation three times, and believed that pelvic abscesses could be better reached and treated by such a method than by abdominal section. He further believed it would ultimately supplant the abdominal method of treatment.

Dr. J. H. CARSTENS, of Detroit, preferred the abdominal method to any form of vaginal treatment. The old method of vaginal incision often left pockets of pus unopened, while the Péan method was a groping in the dark, with unnecessary mutilation of an organ besides.

Dr. J. TABER JOHNSON, of Washington, had had no experience with the Péan operation, but the description of it did not prepossess him in its favor. He had never seen a cure in those cases which were attacked by vaginal incision.

Dr. C. P. NOBLE, of Philadelphia, had seen six cases of undoubted abscess of the broad ligament, the tubes and ovaries being uninvolved. All the cases were puerperal. He believed that in some cases of pelvic abscess the conditions were so unfavorable that the pus sacs could not be safely removed.

The Relation of Urinary Conditions to Gynecological Surgery.

This paper was by Dr. CHARLES P. NOBLE, of Philadelphia. The condition of the kidneys in all cases which were to be subjected to surgical operations upon the genital organs should be carefully studied in advance. An analysis of five hundred cases in the Kensington Hospital in Philadelphia showed that albuminuria was present in ten per cent. of them. The urine in such cases should always be drawn with the catheter, as otherwise errors might occur from the presence of vaginal products. The presence of albumin in such cases was not always to be considered an evidence of serious kidney disease; indeed, it was often the result of interference with the metabolism of nitrogenous food products. The condition was not dangerous when the albumin was due to the pressure of a large abdominal tumor, neither was the presence of tube casts in such cases always of serious significance, but all such cases should be frequently and thoroughly examined. If it should be found that the kidneys were seriously implicated, a prolonged operation would be contraindicated. Death might supervene in such serious cases soon after the operation, even though the immediate effects of the operation were recovered from. The quantity of urine passed by patients during the first few days after abdominal operations had been carefully noted in a large number of the author's cases, and the results tabulated. Even though the operation was a simple one and the kidneys were without discoverable lesion prior to it, suppression of urine would result in occasional instances, with a fatal issue. Severe and prolonged operations on patients with contracted kidney usually resulted fatally. The subject of the influence of ether and chloroform as anesthetics in abdominal operations could not be thoroughly discussed by the author, as he had not yet reached definite conclusions upon this subject.

Dr. A. LAPHORN SMITH, of Montreal, had found that albumin would usually disappear after an operation in the class of cases under discussion, just as it did in pregnant and puerperal women after the termination of labor. An explanation of the small quantity of urine passed for several days after an operation might be found in the small quantity of water which was usually given to patients. He believed that ether was more irritating to the kidneys than chloroform.

Dr. J. TABER JOHNSON, of Washington, had often experienced much anxiety on account of the small quantity of urine passed after operations, and was relieved by the statements made by the reader of the paper. He was thoroughly impressed with the sense of the necessity of prolonged investigation of a patient's kidneys before an abdominal operation was attempted.

Dr. EUGENE BOISE, of Grand Rapids, Mich., believed that suppression of urine after an operation was not necessarily due to serious kidney disease, for there were compensatory conditions in the profuse perspiration which sometimes followed operations and the unloading of serum from the abdominal vessels into the peritoneal cavity. The flow of urine was frequently increased if sufficient quantities of fluid were injected into the rectum after an operation.

Dr. CARSTENS, of Detroit, thought that ether as an anesthetic was often the source of renal injury, but the primary cause of the trouble was to be found in a lesion of the renal plexus. Relief from suppression of urine might sometimes be obtained by means of steam baths, injections of fluid into the rectum, and the hypodermic use of strychnine.

Dr. I. S. STONE, of Washington, thought the subject of the greatest importance. There were cases in which the condition of the kidneys could not be determined in advance. He had once found pus in the renal pelvis of a patient post mortem, though prior to the operation careful analyses of the urine had been made.

Dr. E. W. CUSHING, of Boston, had a feeling of helplessness in the presence of renal complications after operations. Was it not probable that sepsis was present in some of the cases prior to an operation and first manifested itself by renal lesions after the operation? He thought too much stress was laid on the probable influence of the anesthetic in these cases. Again, ligation of the ureters, cystitis, and the use of dirty instruments were all possible explanations of the renal complications. The kidneys were sometimes infected by tumors which were cystic or gangrenous.

Dr. NOBLE admitted the possibility of renal irritation by anesthesia with either ether or chloroform. Ether was not eliminated by the kidneys, however, as chemists had shown. To distinguish between septicaemia and kidney disease was certainly not easy. As had been suggested, a diagnosis of kidney disease before an operation was sometimes impossible. Arterio-capillary fibrosis was a possible condition in some of the cases with renal phenomena. Suppression might also be due to the length of the operation, to the exposure of the body to cold, or to shock.

(To be continued.)

Miscellany.

The Psychology of Queen Christina, of Sweden.—In the July number of the *Alienist and Neurologist* there is a translation, by Dr. Susanna P. Boyle, of Toronto, of an article by Dr. F. De Sarlo, from which we extract the following passages:

"Christina's character is of so complex a kind that at first view it seems to have been formed in order to defy all the definitions and schemes of modern psychological analysis. We do not intend to enter into all the details of her life, but merely to note such important events in it which have weighed with us in arriving at our judgment of her character. To proceed in order, then, we begin by fixing our attention for a moment on the characters of her parents. Her father, the last of the Vasa dynasty, was 'that snow giant' (as he was called by the Emperor Ferdinand, alluding to his golden beard and white complexion) who, by victory after victory, reached the center of Germany, into which, for several centuries, no foreign conqueror had dared to penetrate, and afterward died heroically at the battle of Lutzen. He is judged by history to have been one of the greatest men of his time; of a high, but not haughty spirit; proud, but generous to his enemies; just and sincere to his allies; he assumed in time that air of condescension of superior men who feel themselves above those by whom they are surrounded. His instinctive piety gave a tint of religious exaltation to his courage and made him confound his cause with that of Heaven and consider himself as an instrument of divine vengeance. His numerous victories never, however, succeeded in intoxicating him to such an extent as to deprive him of his clear view of things, for in no researches can we find any notice of a lack of equilibrium in his character, and no baseness or barbarous acts cloud in any way the splendor of his glory, though he lived continually in the field of battle, and had before him as examples the unheard-of atrocities of Tilly and Wallenstein.

Hence, from her father Christina could inherit only good qualities, such as genius, courage, energy, and a tendency toward the magnificent. Her mother was Eleanor, daughter of John Sigismund, Elec-

tor of Brandenburg. She was beautiful, but of a vacillating temperament like her father, excessively vain, weak-willed, and, it appears, but little educated, or at least she occupied a much lower intellectual plane than did her husband. Before deciding how the different characteristics of her parents were fused in Christina, we will speak of the education she had, especially in her early years, for the two influences, hereditary and educative, go hand in hand."

"Christina had always great power over her father—so much that even when she was quite a child he took her with him on hunting expeditions and into the field of military manoeuvres, making her assume, probably for convenience, masculine dress and having her ride at his side. From this it may be deduced, on the one hand, that Christina in her early years received a masculine education, and on the other that she soon became *Penfant gâté* of her father. What would Christina have become had her father not been compelled to leave her when she was four years old, in order to go to the Thirty Years' War? We shall not attempt to solve this problem, but certainly, judging from what she afterward became on account of the absence and death of her father, it may be argued that her life would have been a very different one. However, Gustavus Adolphus died and Maria Eleanor kept her apartments always in mourning, their darkness being broken only by melancholy ceremonies. At the head of her bed she had suspended a golden casket containing the heart of the deceased. She would lament and weep for hours and wished the young Christina to assist at these functions, making her sleep with her in order to have her always present at these scenes.

"Besides the five great crown officials, assigned by her father as tutors, there were others who contributed, as Claretta observes, to give her false conceptions of things. There is no doubt, however, that Christina was by nature very precocious, for the fact that she became very soon disgusted with the atmosphere in which her mother and tutors wished to compel her to live proved that she had already reached a degree of development beyond that proper to her years.* She rebelled and refused to follow the same kind of life, and gave herself up to her studies. Stearn considers that these studies were absolutely preternatural. At ten years she gave twelve hours a day to mathematics and languages; at sixteen she had already mastered six languages, and understood literature, music, and archeology; at eighteen she presided over the Senate. She wished to understand everything, for nothing was difficult to her, so versatile and highly gifted was she. Just as her father's conquests and victories had been unlimited, so she seemed to think there were no bounds to knowledge; and it is probably no exaggeration to affirm that Christina surpassed in talent and knowledge all the noted women of history. Although she was strong and robust, the dedication at ten years of age of twelve hours a day to mathematics and languages was not a thing which could be done without leaving some effect, and it seems to us this must be given a place as one cause of subsequent exhaustion.

"Every one knows what a great influence is exercised over the minds of the young by the people surrounding them, and it is noteworthy that Christina was surrounded by individuals who were in every way unsuited to her. Instead of being with people of her own age and sex, she was always with adults and men, who could only admire her and thus favored her inclination to immoderate studies and prolonged labors. Thus the education imparted to Christina, which was of the most foolish and erroneous kind, gives us in part the key to her future life. A child who should have devoted the greater part of the day to pastimes and recreations was placed instead in totally unsuitable surroundings. It may be imagined what a mistake was made when a child of such precocity as Christina was placed in relation with scientists, such as Grozio, Cartesio, Vossio, Ireisheim, etc., and also with a French doctor, Michon, *alias* Bourdelot, the son of a barber, who, with

his arguments and vacillating principles, succeeded in gaining the esteem of the young queen."

"The fact is that at the age of twenty-two years she presented a notable change in her character, and, while at first she had been all intent on governing, she now became exhausted and tired and desired to lead her life according to her own fashion; while at first she had shown energy and strength of will in attending to the well-being of her subjects, she now showed herself frivolous and immoral, so that we seem to recognize in her a second personality superimposed on the first. What reason can be given for this change? Is it to be attributed to hereditary influences? It is known, in fact, that children not only inherit contemporaneously in a mixed fashion the characters of both their parents, but can also inherit for one part of their life the character of one, and for another that of the other parent. In this case Christina in youth and adolescence presented principally the characteristics of her father, and in maturity those of her mother, becoming vain, frivolous, extravagant, intriguing, and capricious. It is certain, however, that the fundamental qualities of her father (knowledge and energy) were never lost, but were, so to speak, covered and overpowered by those of the mother. Or is the above-mentioned change in character to be attributed to the difficulties met with in her government and the disillusionizing consequent thereto? One of her biographers says that she had a great mind not weakened by struggling, a tendency to the great and magnificent, but at the end '*rimace vinta*.' We, truly, can not give preference to one cause more than another. To us it seems that both, though we attach greater weight to the hereditary influence, served to prepare the way for the development of the two most important events of Christina's life—viz., the abdication of the throne and her abandonment of the Lutheran religion.

"At first sight to search, to explain such events, seems an exceedingly difficult undertaking; but if we take into account, on the one hand, the changes which Christina's character underwent when she was twenty-two years of age, and, on the other, the atmosphere in which these events developed, all becomes clear and evident. Christina had one of those enthusiastic natures, passionately devoted to their ideals, for the attainment of which they will make any sacrifice whatever. She had inherited from her father the faculty of bringing every energy to bear on the completion of the most difficult enterprises, and it was in consequence of this that in her youth she dedicated herself entirely to the administration of the government of her country, in which she gave proof of uncommon strength and wisdom. She had hoped that her efforts would be crowned with success, and that she would be able to succeed in really giving to Sweden that importance in Europe which she had eyed longingly from childhood; but she soon perceived that her dream would never become a reality, and it was her bright intellect, which never lost its clear vision of matters, which contributed in great measure to undeceiving her. A less ardent, less cultured nature would probably have resigned itself to the course of events, would, so to speak, have allowed the stream to run its course, and would have called for aid from influential personages; but Christina, who, as we have already said, at her entrance into maturity began to present the characteristics of her mother (frivolity, vanity), neither had the strength to fight nor could resign herself to her fate; hence the resolution, which appears so strange, to abandon the throne; which resolution was merely the reaction of her spirit to the obstacles opposed to the realization of her ideal."

"Now [after her abdication] there was an almost complete transformation in her; her ideas of liberty and complete independence at last found ways to express themselves, without being first detained in the Nesso chamber of court ceremonial. Her mind had now shaken off the burden of thoughts of the administration of the Government, and she felt for the first time really mistress of herself. And, just as much as her tastes and inclinations in the past had been repressed and kept in abeyance, just so much in the reaction now they claimed to be gratified, and every day it may be said that she imposed on herself new duties; felt new needs of which in the past she had probably never even thought. Everything that was methodical, measured, or limited fatigued her, everything that was formal or conventional bored her;

* How independent and indifferent she is shown by the following anecdote: Her mother having one day reproved her by saying that had her father lived he would not have consented to so many pastimes and amusements, she did not hesitate to answer that in that case it was better he was dead. We can not deny that such a reply from a child betokens a character far from affectionate.

all the '*sericit nordica*' (northern gravity) must give way before the great disturbance of her mind, which now desired to wander as freely in the field of art as in life. From this arose the thought of abandoning her native land and going to Italy—that country in which art and Nature seem to have united to make the sweetest of dwelling places.

"Christina at this time felt the need of cutting herself loose, so to speak, from all that bound her to her past life; she, wishing to destroy all that northern gravity, naturally felt that in order to do this it was necessary to abandon the principles on which this was founded, and was the cause of it. Such a foundation was, as every one knows, furnished by the Lutheran religion. Hence it was that Christina hesitated not an instant to form the resolution to complete the act which would make her an alien to her native land, and which must bring her on the one hand many friends and adorers, but on the other furious enemies. . . . An abjuration made by a woman like Christina, intelligent and cultured, is a matter worthy of our attention, for it is a complex psychological phenomenon, especially when we consider that she who was led to take such a step was the daughter of Gustavus Adolphus, who was known as the 'Paladin of Protestantism.' Many have said, perhaps in order to make trouble, that Christina's abjuration was only one of the numerous peculiar actions she was in the habit of doing; others, that it was merely an act of convenience, so that she could go to Italy and be received and *fêted* by the Pope; others (Stearn), that it was merely her artistic soul that caused her love of Catholicism, but that she was really an atheist. What is the truth? Certainly Christina was not possessed of a very religious nature, and to this her excessive culture had in part contributed, but, above all, her intimacy with the atheistic Dr. Bourdelot, her favorite, was to blame; but it does not seem to us that Christina was a thorough unbeliever, and that it was an act of hypocrisy on her part to solemnly embrace Catholicism, when we take into account her great mental gifts, among which were sincerity and loyalty, of which she proved herself possessed always. To us, therefore, it seems that Christina had a fund of religiosity, which had assumed a determinate and stable form, and that she, finding herself in a struggle with use, custom, and northern traditions, instead of giving the preference to the Protestant form of religion, felt herself attracted to Catholicism, which had the advantage of appealing to the artistic side of her nature. She who so loved all kinds of amusements and diversions allowed her fancy to be taken captive by the externals and all the luxuries which surrounded Catholicism. But certainly neither had the Pope cherished the illusion of making an ardent devotee of her, nor had she any hesitation in exposing the machinations of the popes, cardinals, bishops, and priests."

"It would take too long to give in order and in detail all the events which took place in Italy during the sojourn there of the Queen of Sweden; this has been admirably done by Claretta. It is of interest to us only to note in passing such deductions as may be drawn from his narrative regarding the psychology of Christina. The characteristic which strikes us most forcibly is her great fickleness and contradictoriness; to-day she desires that which she did not wish yesterday, and to-morrow she will certainly not want what she desired to-day; at times she is disgusted with the different popes, and we see her showing herself as energetic, careless, disrespectful, and sometimes also ungrateful, but only allows a few days to pass and behold she becomes humble, prompt to bow her knee and implore pardon. In the course of a few more days Christina again becomes bad-tempered, irritable, despondent and disposed to cast everything in the teeth of the Pope. The contradictions in which she enveloped herself were absolutely innumerable, and indeed it may be said that her mind lived by contradiction; she loved simplicity, but woe to him who came before her less the smallest particular of ceremonial—so much so that the greater part of her troubles with the ambassadors of the various European powers, and with the members of the Roman College, proceeded from faults of this kind. She abandoned her kingdom in order to live a free life, and full of faith and enthusiasm she went to Rome, but after a little she became tired of this and wished to return to rule in her own country, but not being able to do so, she even thought of laying claim to the throne of Poland." . . .

"Another characteristic brought to light by the account of Chris-

tina's actions during her sojourn in Italy is the strength of which her actions all speak. She had a proud desire to do everything differently from other people, to appear singular in all her actions as in all her tastes and opinions. The greatest disrespect which could be shown to her was to imitate her; in such a case she either flew into a rage or suddenly had recourse to some other stratagem by means of which she would be the only person to do things in a particular way. It was for this that she showed such a mania for protecting the worst kind of wretches and all those elements which constituted the refuse of society.

"It is not necessary to dwell long on the tendency of the Queen to pastimes, diversions, and feasts, for we have touched on that above, but it would be well to call attention to her egoism, which, it may be said, transcended all her other characteristics. No lasting or deep affections are met with in her, outside of her love of her own personality; if ever any trait of generosity is found, it is always done with a utilitarian view, hoping that the good she did to others would reflect on herself. More than once she showed herself ferocious and inhuman, and it was always when 'Her Most Gracious Majesty' had been in some way offended. And, though recognizing that the finances of the Pontifical Court were at that time in anything but a prosperous condition, and that in order to cover her heavy expenses they must burden the poor Romans with taxes in one disguise or another or neglect their looks of benevolence, she never hesitated to demand money from the various popes, and they for political reasons were compelled always to give it. The sojourn of Christina in Italy was indeed a calamity, as far as the pontifical finances were concerned.

"So, to make a *résumé*, we may say that the leading characteristics which Christina showed during her stay in Italy until her death, at the age of sixty-three years (in 1689), were immorality, fickleness, vanity, a mania for making herself 'interesting,' numerous contradictions of character, and egoism. This is sufficient to enable us now to begin to formulate briefly our judgment of her mental condition.

"It must be agreed that the psychological physiognomy of Christina of Sweden is not one that appears complete at first sight and on a superficial examination; on the contrary, it presents many aspects, and, like a polyhedron, has many faces. The fact that she succeeded so soon in finding her level is a proof that her intelligence found itself in antagonism with the surroundings in which she lived; she did not understand, in fact could not adapt herself to, the knavish customs, the numerous prejudices, the empty formalities which, especially in matters of religion, at that time predominated. She felt herself at a disadvantage in the midst of those cardinals and prelates whose lives were so at variance with the spirit of Christianity. The politics of the time also aroused her anger, and nothing was more common than to see her applaud a generous act on the part of some State or blame some indecorous action. Any one considering Christina only from this point of view could do no less than judge her a woman of genius who was far in advance of her time. But, besides her high intelligence, her love of classical studies, her taste for the arts, there must be noted her tendency to intrigue, to commit mean acts, to condescend to acts unworthy not only of a queen, but of any gentlewoman, and to push herself into matters which did not concern her. All these things prevent her from being placed in any ordinary classification. Thus the lack of uniformity in her thoughts and in her actions is the fundamental characteristic of Christina's mind, a lack of uniformity which shows a weakness of will-power and energy and of that particular power which constitutes the nucleus of a human personality. Without this, indeed, it is impossible to have unity of thought and act which makes an individual at harmony with himself. Christina had normal perceptions (she never had visions nor hallucinations), a lucid, quick intelligence (as shown by her writings), but a weak will.

"And emotivity? Regarding this we find in her what is present in all those who lack those inhibitory powers which contribute, on the one hand, to give unity to the character, and, on the other, impede continuous and partial reactions to single impressions, and, being an obstacle to incessant loss of energy, cause the emotions to develop in the mind in a slower and more orderly but more intense manner; she had also a tendency to go in search of all those extraordinary facts which, by their singularity, were capable of stirring up her whole nature. In such a character is linked the restlessness peculiar to the queen, which,

fearing neither discomfiture nor repulse, ventured always on something new, and also her mania for going in search of exceptional cases.

"It has been said that Christina was exceedingly imaginative and fantastic, and this is so. The vastness of her culture, the brightness of her mind, and the uninteresting surroundings in which she lived, all contributed to make her so. The great difference between her ideals and her real life would naturally carry her away and advance her further into the realm of dreams."

"Now, in the case of Christina, is a definition of her mental disease possible? Is it possible to make a diagnosis of her affection? We believe and frankly say that the psychological characteristics met with in her authorize us to state that Christina, in our judgment, was the victim of *hysteria*. Nervous pathology, indeed, admits a peculiar disease, characterized by a complexity of the most varied phenomena, of which there are a few which are capable of leading us to a safe diagnosis. These are: egoism, vanity, contradictoriness, moral insensibility, a tendency to be fantastic and to wander, frivolity, and a lively intelligence, all of which may for the most part be regarded as consequences of a weak will.

"And with this the psychopathology of to-day would have made answer. Now it seems to us that there is room here for investigation, as to how far modern science can be benefited by such an answer. In the past it appeared quite an advancement to be able to judge by means of a formula or to incorporate in a scheme a given historical figure which till then had been regarded as extraordinary; and it can not be denied that thus, on being successful in classifying among diseases of the human brain some of those which had been reputed 'divine actions,' we have shown a progress in knowledge. But now a new exigency presents itself; we may content ourselves with a simple definition of the mental state of an historical personage, but we wish to know in what relation the development of a given form of mental disease stands to the surroundings in which the person lived, as, on the other hand, it is necessary to know the part played by the disease in the accomplishment of the person's acts. It is only after having answered such questions that we can be said to have interpreted an historical individual by the light of psychopathology. If we had stopped at the simple definition of Christina's mental state, characterizing her as hysterical, what should we have done? We should have expressed comprehensively, in a single word, the whole of her psychological character, but science and history would have gained nothing. Hysteria, in fact, expresses a group of the most diverse phenomena, which may be determined by numerous causes, and until we have succeeded in ascertaining these we signify by the word *hysteria* only a number of symptoms deprived of any real value. In the case of Christina, for example, that assemblage of symptoms (egoism, vanity, frivolity, weakness of will) which we have called hysteria, may well have been due to other causes, and also have been produced very differently from those of any other form of hysteria; and the task of historical psychopathology is to exactly place *en evidence* the cause and evolution of a given pathological form in relation to historic surroundings. It must be borne in mind that morbid conditions of the mind are not like common diseases, each of which has a cause, progress, anatomical basis, course, and fixed termination. In every case, on the other hand, it may be said that there is something peculiar and special, for each person has a different mental constitution and lives in different historic and social conditions. And if we consider the events of Christina's life we are at once convinced that, had she been educated differently, and had she been able to apply her genius and excess of mental energy to great and glorious enterprises, she would not have appeared to us as hysterical. Hysteria, indeed, in her was not something decreed by fate which she had inherited from her ancestors, nor had it followed one or more definite causes, but it represented the epilogue of a great battle of elements and the final result of the great opposition which her intellect encountered in the surroundings in which she lived.

"Hysteria, therefore, represents the termination, the consequence, the causes of which may be most diverse, and until we have determined these we can not be said to have interpreted psychologically a certain historical period, but only to have expressed in a word what was formerly done in more than one. What fundamental difference exists

between saying Christina was hysterical and affirming that she was of a giddy, egotistical, capricious, fickle, weak character? None, it seems to us; but if, on the contrary, we can show in what way her mind, in given conditions, developed gradually; if we try to show clearly how her mind, partly by hereditary influence, had been constrained to model itself into a certain shape, and if, finally, we follow the action which the spirit of her century exercised over her will, then shall we have reconstructed, scientifically, an historical figure. In such a case the diagnosis of hysteria becomes an accessory fact to a long series of matters which are very important and worthy of recognition. Hysteria is not, therefore, the fundamental cause which determined the course of events of Christina's life, and gave to it its peculiar psychological physiognomy, but is only the external expression or the effect of profound internal factors. It is clear, however, that we can not deny that many of Christina's acts must be attributed to the hysterical turn of temperament which developed in her; but these are only secondary, accessory, or subsequent."

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Contributors who wish to order REPRINTS of their articles should do so on a blank prepared for that purpose, which will be sent to them by the publishers on receipt of a request to that effect. The order should be sent to the publishers, and not to the editor.

Original Communications.

TENORRHAPHY,

WITH CLINICAL REPORT OF CASES.

By FRED. B. LUND, M.D.,

BOSTON.

WOUNDS and injuries involving the section or rupture of tendons present to the surgeon cases of great interest and often of the greatest difficulty. Being commonly caused by accidents in the employment of tools or machinery, by cutting or crushing implements, the greater proportion of cases occur in laboring men, and concern the tendons of the hand or wrist. The usefulness of a hand depends so entirely upon ability to move the fingers freely, to grasp and let go, that the damage caused by a single knife stroke which severs the tendons of the wrist or the palm may entail total disability in a trade. In these cases the livelihood of the patient and of his family, if he has one, depends upon the success of the surgeon's efforts to restore the lost function.

Until recent years such injuries have been classed among the most hopeless which were presented to the surgeon. In preantiseptic days, owing to the well-known rapidity with which septic inflammatory processes spread along the tendon sheaths, the danger to life in these injuries from lymphangitis, septicaemia, etc., was not a small one. Fortunately if he escaped such dangers as the result of the injury in the first place, the patient was doubly so if no such untoward result followed the efforts of the surgeon (when such were made) to repair the damage. Hence the well-known reluctance of surgeons to attack these injuries in preantiseptic days. So great was the danger of septic infection that they rarely interfered, such interference meaning really the risk of a life to restore, often partially, the use of a limb. A successful tendon suture contributed more to a surgeon's reputation for good fortune than good judgment.

In preantiseptic times, then, the section of a tendon meant, at best, the permanent loss of function of the member supplied by it. The ends separated by the action of the muscles became so fixed and anchored in a firm mass of cicatricial tissue that, instead of enabling its own muscle to move a limb, the tendon held the limb fixed, and effectually prevented the opposing flexors or extensors from acting. The mass of cicatricial tissue about the severed ends often involved neighboring tendons, if they ran close to the injured one, so that section of a single deep flexor at the wrist, for instance, might involve disability of all the other fingers of the hand. It is well known that the co-operation of its opposing extensor is as necessary to the action of a flexor as its own free motion, and *vice versa*.

When we consider the dangers involved in suture of tendons before antiseptic methods were introduced, we will not be surprised to find the literature of the subject extremely limited, and the reports of cases very few. With the advent of antiseptic methods, however, the status of

this operation became entirely changed, and its safe and easy performance is not one of the least of the benefits which have come to surgery and humanity from the teachings of Sir Joseph Lister. The great danger—that of sepsis—can and should be avoided by the precautions which it has become the duty of every surgeon to undertake; nor is he deterred by this danger from undertaking complicated operations, involving much manipulation of the tendons and their sheaths. On the contrary, the results in these cases are so gratifying in respect to restoration of function that they now present a most attractive field for surgical work. In the year 1876 Küster, at the German Surgical Congress, called attention to the brilliant future which the Listerian treatment had opened for the operation of tenorrhaphy. His prophecy has proved true. In the light of modern results, it is almost malpractice not to unite by sutures the ends of severed tendons. The contrast with former surgical opinion is manifest.

In later years still, the method of treatment by aseptic blood clot, brought so prominently into notice by Schede, is believed by many to have greatly improved the prognosis as to completeness and rapidity of recovery in these cases. For the reason that the cases which have come under his observation have all been treated by careful hæmostasis, with or without drainage, the writer is able to contribute no direct clinical evidence upon this subject. A review of the arguments in its favor will, however, be presented, and it will be found that strong clinical evidence has been adduced in its favor.

Considering the frequency with which the suture of tendons is performed nowadays, it is surprising that so few results have been published. The reason for this may perhaps lie in the fact that the operation is most often performed in the accident rooms of hospitals and that the ultimate result may often not be judged for six months or a year. After their discharge from the hospital it often becomes a matter of difficulty to get patients of this class to return for observation, so that the final results are rarely entered on the hospital books. The cases to follow are all of the cases performed at the Massachusetts General Hospital within five years which the writer could induce to return for observation, although attempts were made to secure a much larger number. There have been published, however, three series of cases in which the final results have been reported, and the effect of the special circumstances of each case upon the result discussed in detail. These are, namely: 1. A series of thirty-four cases treated at the Hamburg General Hospital, reported by Wolter;* (2) fifty cases from Billroth's Clinic at Vienna, reported by Schüssler;† and a series of eight cases reported by Schreiber‡ in the *Münchener med. Wochenschrift* for 1890. It is hoped that the cases discussed in this paper may throw some light on the prognosis of these injuries, more especially in showing what good results can be attained

* Wolter. *Langenbeck's Archiv*, 37, 8, 157.† Schüssler. *Schnellnahme an der Klinik Billroth*, Wien, 1890.‡ Schreiber. *Münchener med. Woch.*, 1890, 8, 499.

when the unfavorable complications of fracture of the bones and crushing of the soft parts are present. Owing to the tough and unyielding nature of tendon tissue, it is rarely torn apart except by tearing or crushing injuries which lacerate the soft parts and often break the bones, so that the surgeon meets with about as large a number of such cases as of clean knife strokes.

Diagnosis.—The diagnosis of section of a tendon presents difficulty only in the case of small incised wounds which can not be made to gape so as to permit investigation of their deeper parts. In these cases the diagnosis must be made by careful examination for loss of function in the member or members of the tendons exposed by their anatomical position to injury. We must here take especial care to exclude the effect, first, of pain, in preventing the patient from voluntary effort to move the member, and, second, the effect of the support of one member by another. A patient, for instance, can easily extend the middle finger after section of its extensor tendon if the neighboring fingers are closed against its sides, while independent extension—i. e., with the fingers spread out—will be impossible. The anatomical conditions must be carefully weighed in each case. After section of the long extensor of a finger over the back of the hand, for instance, if the first phalanx is flexed, the terminal phalanges may be extended by the action of the interossei and lumbricales, which will in this case be inserted into the peripheral portion of the severed tendon. The above sources of error being excluded, loss of function in a tendon exposed to injury by its position means section of the tendon. When these sources—as that of pain, for instance—can not be excluded, the wound should be enlarged, and search made for the peripheral end, which can always be made to appear in the wound by hyperextension or flexion, as the case may be. The thorough disinfection of a wound ought often to involve its enlargement to a sufficient extent to enable the surgeon to examine as to the structures injured.

Prognosis.—The subjects of prognosis and treatment, and of prognosis as affected by treatment, form the most important part of our discussion. We are to try to answer the question, What advantage can we promise a patient in any given case will result in his undergoing an operation for suture of a tendon or tendons? The answer to this question has been first systematically and thoroughly made by Wolter in the paper alluded to above, and in the discussion of the effect of varying anatomical conditions the author will, in the main, accept his conclusions, some of which have been verified by abundant clinical experience, and some of which the writer has himself verified both by clinical observation and experiments on the cadaver.

To attain a good result in any given case, as Wolter has pointed out, we must secure two objects: 1. The restoration of the continuity of the tendon and of its normal length, either (a) by primary union of the severed ends, (b) union of the ends by a "callus" of connective tissue, or (c) union of the ends by adhesion of both to a cicatrix of skin or tendon sheath. 2. Preservation of the normal mobility of the tendon. Whether or not we are to attain

the above essentials in a given case will depend upon (1) the anatomical relations of the tendon at the point severed, and (2) upon the progress of the wound. To these we might add (3) the presence or absence of concurrent laceration of the soft parts or fracture of the bones.

We are to consider, then, first, the anatomical relations of tendons as affecting repair and subsequent mobility. Tendon tissue is tough and slightly vascular, deriving its blood supply chiefly from its sheath, which is abundantly supplied with blood-vessels. In repair of tendons, as of other tissues, a more abundant supply of blood is required than for growth or the repair of ordinary waste. The loose cellular tissue which forms the sheath of certain tendons—as, for instance, the extensors over the back of the hand—is much more abundantly supplied with blood than the dense semicartilaginous synovial sheaths which envelop the flexors of the fingers, for example. Therefore we would naturally expect firmer and more rapid repair in the former class of tendons than in the latter, and clinical observation and experience teach us that this is the case. Again, as tendons depend for their repair largely upon the supply of blood derived from their sheaths and other adjacent structures, these adjacent parts will be always found more or less adherent to the tendon cicatrix. Now, if these adhesions be to fixed parts, as to bones or the thecae of the flexors over the fingers, the motion of the part will be prevented unless these adhesions can be gradually broken up without rupturing the newly united tendon, whereas if they are to movable parts—as in the case of adhesion of the extensors over the back of the hand to the skin—the latter may move freely with the tendon without prejudice to function. In the latter case, even where the ends of the severed tendon can not be brought together, the skin cicatrix may be made to supply the gap without prejudice to the function.

Another factor indirectly affecting the prognosis will be the varying amount of retraction of the central ends. When the retraction is greater, the surgeon will have to resort, in searching for the ends, to means involving greater injury to the sheaths and surrounding soft parts, thus increasing the liability to the formation of adhesions. An extensor divided over the back of the hand, for instance, will only retract about two centimetres, further retraction being prevented by the fibrous bands which connect it with the skin and fascia, and will be found at the bottom of a funnel-shaped depression in the tissues. A flexor divided at the wrist, however, may retract three centimetres or more, and must be searched for in the depths of a long synovial canal. The effect of the anatomical conditions upon prognosis will be further considered when we take up the different classes of tendons in detail.

After the anatomical conditions, our next factor, and one of the greatest importance, is the progress of the wound. The manner in which the wound heals is of the greatest importance, as determining whether our result will be injuriously affected by the formation of extensive adhesions to surrounding parts. The healing of the wound depends upon three varying conditions:

1. The manner of its infliction.

2. The extent of concomitant injuries to surrounding parts.

3. The method of wound treatment adopted by the surgeon.

As to the first consideration, the prognosis will, of course, be better where the wound is made with a presumably clean than an undoubtedly septic instrument—with a planing tool than with a fish knife, for instance. In this regard, however, almost everything depends upon the thorough disinfection of the wound by the surgeon. The most unfavorable wounds can be made to heal *per primam* by thorough irrigation with corrosive sublimate (1-2,000 to 1-5,000), and all wounds in which free access to the depth can not be obtained should be enlarged for this purpose. In these cases irrigation is as important a means of treatment as in the somewhat similar class of compound fractures. As to the second condition, it is evident that the greater the concomitant laceration of tissues the greater will be the amount of exudation, and the larger the resulting mass of cicatricial tissue, and consequently the firmer the adhesions. Upon the same principle the methods of the surgeon in finding and securing the retracted ends should be those which entail the least bruising or tearing of the tendons themselves and of the parts with which they are in relation. This leads us to a consideration of the method of performing tendon suture.

Anæsthetics.—Cocaine and ether may be employed in these cases, and both have their supporters. For the majority of cases the employment of complete ether anæsthesia seems to the writer by far the safest course. Cocaine has been recommended as enabling the surgeon to employ voluntary motion on the part of the patient as a means of identifying severed tendons. This advantage, which is but slight when the surgeon possesses adequate anatomical knowledge, seems to me more than counterbalanced by an accident which he has seen more than once under cocaine anæsthesia—namely, that some sudden pain unintentionally inflicted by the surgeon causes a spasmodic contraction of the muscles of the limb, which tears out all the sutures and renders necessary the retracement of all the steps of the operation. This is both annoying to the surgeon and prejudicial to the result. Ether, on the other hand, if employed to complete anæsthesia, prevents such accidents by the relaxation of the muscles which it causes, and by rendering the patient totally insensible to the pain which might induce them to contract. This advantage is of especial importance in the case of sensitive, nervous patients. Another advantage of the greatest importance which ether anæsthesia gives the surgeon is the opportunity to employ the scrubbing brush in disinfecting the surrounding skin, a process which, without ether, causes often unendurable pain. After etherizing and disinfecting our wound by irrigation with corrosive sublimate, the next step is to find and secure the severed ends of the tendon.

Methods of finding the Severed Ends.—For this object we should always begin with the method which is the simplest and involves the least laceration of the delicate structures with which we are dealing. If these means fail, we may then resort to methods involving greater injury to

the tissues. In the first place, it is a waste of time to begin our search before hæmorrhage has been stopped by the application of a tourniquet. (In wounds of the forearm and hand the tourniquet should be applied above the elbow so as to avoid including the muscles with which we are concerned.) If after the hæmorrhage has been stopped the ends do not appear in the wound, we will probably be able to find the peripheral end by flexing the part to which it runs if it be a flexor, or extending it if we are searching for an extensor. The end may thus easily be made to appear in the wound. A similar manœuvre which is sometimes effectual in bringing the central end into view consists in applying the Esmarch bandage to the limb *from above downward*, so as to crowd the muscle downward and stretch it.

If the above methods, which are to be preferred as involving absolutely no handling of the wounded parts, are unsuccessful, we may next proceed to enlarge the wound transversely, so as to get a view of its depths. In this way we may often succeed without the employment of longitudinal incisions, which, however carefully made, complicate the wound and facilitate the formation of adhesions. If we are unsuccessful by this means owing to the depth to which the end has retracted, we may have recourse to longitudinal incisions, which are not to be made directly over our tendon, starting from the wound, but best in one of the two following methods:

The first method, which is to be chosen in the great majority of cases, is that brought prominently into notice by Oscar Witzel,* of Bonn. It consists in making our incision, starting from the original wound, not over the tendon, but parallel to and at a slight distance from it. The skin flap is then dissected up until we recognize the gleam of the tendon shining through its sheath, and the sheath then opened only as far as is necessary in order to reach the tendon. We can then suture the wound in the sheath with buried sutures, and when we have completed the operation and sewed up the skin, we have our skin wound at a distance from that of our tendon and sheath, and thus avoid, in large measure, the danger of adhesion between the two. If, on the contrary, the wound in the skin lies directly over the tendon, adhesions of the two cicatrices along the whole length often result—in fact, we get one common cicatrix for both. Where two tendons are cut, one incision parallel to and between the tendons will answer for both. This method is obviously to be chosen in all cases where we have to deal with tendons running in loose connective-tissue sheaths, as over the back or in the palm of the hand, and also where the tendons run close and parallel to each other in a general synovial canal, as do the flexors of the wrist.

Where, however, we have to search for a tendon lying in a single, narrow, definite synovial canal, as in the flexor of a finger opposite the phalanx, the method of Witzel should give place to one which involves the least possible wounding of the synovial sheath, or at least wounds the sheath at a distance from the point where the tendon is

* Witzel. *Sammlung klinischer Vorträge*, Leipzig, 1886, S. 291.

severed. Here we have to avoid adhesion to the stiff fibrous sheath, as greatly more dangerous to our prognosis than adhesion to the skin. The second method, which bears the name of Madelung, is as follows, and is designed to take the place of the blind process of fishing for the end of the tendon down the canal with forceps or hooks,* which should be deprecated as an unsurgical procedure and liable to lacerate the end of the tendon and wound its sheath:

A longitudinal incision one or two centimetres long is made over the tendon, beginning about two centimetres above the original wound. This distance will vary according to the distance to which it is estimated the end has retracted. Open the sheath at this point, seize the end of the tendon, draw it out through the new wound, and pass a strong suture through it. Tie the end of the suture to a probe, which is then passed in at the new wound and out at the original one. Then, by pulling upon the suture, draw the end of the tendon down to its original position, where it is to be sutured to the peripheral end. By this method we avoid unnecessary laceration of the end of the tendon, which is so prejudicial to primary union, and above all avoid a T-shaped wound in the sheath, which would be sure to result in the formation of strong adhesions. The method of Witzel was followed in all but one of the fifty cases reported by Schüssler from Billroth's clinic, in the one case Madelung's method being employed.

Such being the best methods for finding the ends, our next object is to secure them firmly in good apposition, so as to avoid the too common accident of a separation of the ends. Much will depend upon the choice of proper

Needles and Suture Materials.—Our main object throughout the operation being to cause as little bruising and laceration as possible, we must choose needles which will pass smoothly through the tendon, leaving a round, clean puncture. The common glovers' needles, with their three prominent angles, are to be discarded. It is best to employ either round needles or the saber-shaped needles of Hagedorn, which, when introduced flatwise to the tendon, separate its fibers so as to leave a barely perceptible slit. For suture materials, the surgeon has commonly at hand silk and catgut, either of which may be employed. With catgut it has seemed to the writer that there might be danger of a too early absorption depriving the tendons of their support before they had sufficiently united and allowing them to pull apart. Clinical experience, however, seems to show that catgut is a safe suture material. In Wolter's thirty-four cases catgut was employed, and no separation of ends is reported. The catgut was uniformly absorbed, never appearing in the wound. In Schüssler's series of fifty cases silk sutures were uniformly employed. In all but four of them the silk was absorbed; in four cases the silk sutures were extruded, without supuration, however, and apparently without prejudice to the results, which were good. In one of Schüssler's cases an extensor tendon pulled apart after an interval of five weeks, and in another, a flexor after seven; but it would seem that after these lengths of time had elapsed the accident would

be more likely to be due to too active employment of the newly healed tendon than to any fault of the suture material. A similar case is the one reported by the writer,* of suture of both flexors of the forefinger with silk, where too energetic passive motion caused the ends to pull apart after two weeks. In the cases reported in this paper equally good results have followed the use of both suture materials. On the whole, since catgut, if aseptic, never appears in the wound, it would seem to the writer preferable to silk; for the extrusion of silk must carry with it a *possibility* of infection, which does not exist in a perfectly healed wound. Silk, however, has the great advantage of being much more easily prepared for use, and its employment for tenorrhaphy can not be considered bad practice.

Methods of Suture.—It is a common experience, as has been noted in discussing anesthetics, for a suture, either from sudden contraction of a muscle or from too great tension brought upon it by the surgeon, to pull out of the end of the tendon and have to be replaced. The reason for its frequent occurrence is that the sutures which hold tendons must work at a disadvantage, having to pull in the direction of least resistance—namely, parallel to the fibers of the tendon. This accident can almost always be avoided if the sutures are placed so as to make tension not entirely parallel, but at a slight angle to the direction of the fibers, as is the case with the quilt and the "Billroth" suture, which are to be described. Sutures simply passed through the end of the tendon and tied will hold if enough of them be employed. The method recommended by Witzel depends upon these alone, and has given excellent results in practice. It consists in passing a single "tension suture" of coarse or medium catgut through both ends of the tendon at a distance from the point of section, drawing by this the ends together and tying it. The edges may then be accurately approximated by finer sutures of adjustment (Fig. 1).

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

A method which combines the advantages of being easy to execute and of bringing the tension of the suture against a greater resisting surface and in part transverse to the fibers, is a modification of the quilt suture described by Wölfler,† which will be easily understood by referring to the diagram, bearing in mind that at each interruption in the suture line the needle is passed clear through the

minutiv hooks have been invented for this particular purpose.

* Case XIV.

† Wölfler. *Wiener klinische Wochenschrift*, 1888, vol. i, S. 1.

tendon, and back again at the next, so that on section our suture will look like Fig. 3.

The method employed in Billroth's clinic consists in including a bundle of fibers from the side of the tendon in each suture, tying the suture around that bundle, including a similar bundle from the other end of the tendon, and tying that also. So that when tension is placed upon the suture, its direction, instead of being parallel to the tendon fibers, is almost at right angles. This method has been objected to as likely to cause strangulation and necrosis of the included fibers. In practice, however, it has given excellent results, and the above objection has not been found to obtain.

Where there is great danger of tension on the sutures, the method of Nicoladoni may be employed. This consists in fixing the central end of the tendon to the skin at some distance above the wound by an acupuncture needle or deep suture. The ends of the tendon are then united by ordinary sutures. The quilt and "Billroth" sutures are simpler than this, and are to be preferred in general. Operations for supplying a defect in a tendon, however, where we may find difficulty in suturing with the requisite strength, may be greatly facilitated by this method.

Wound Treatment.—Three methods are open to us.

1. Partial hæmostasis and suture of the wound without dependent drainage. (Moist blood-clot method.)
2. Thorough hæmostasis without drainage.
3. Thorough hæmostasis with drainage by gauze* or tube.

When the wound shows crushing or laceration of the soft parts, there can be no question but that drainage should be employed. In the case of clean incised wounds, however, our course is not so clear. Wolter in the paper above quoted has given an excellent argument for the employment of the moist blood-clot method, and supported it by excellent clinical results. His arguments in the main are the following: Repair in tendons takes place, as pointed out by Volkmann,* not by a reproduction of tendon tissue, but by the formation of a mass of connective tissue around and between the ends. The non-vascular tendon tissue contributes but little to the formation of this "callus," if so it may be called, the main part being played by the vascular sheath and surrounding tissues. From the abundant vessels of these tissues takes place the diapedesis of leucocytes, the throwing out of capillary loops—in short, the formation of granulation tissue. This granulation tissue becomes later the cicatricial tissue which holds the ends in apposition. This mass of cicatricial tissue necessarily limits the motion of the tendon at first, but later almost disappears, with exercise of the part, except the thin layer between and just around the ends, which comes strongly to resemble true tendon tissue. On this basis Wolter accounts for the well-known fact that those tendons which run in sheaths of loose connective tissue heal more rapidly and firmly than those which lie in firm, dense synovial canals, as the flexors of the fingers. In the latter case the blood extravasation will be too slight, and the

formation of granulation tissue insufficient; the granulations, feeble in themselves, will not find blood clot enough to feed upon. On this ground he argues that complete and careful hæmostasis is prejudicial to the most complete and rapid repair. We should encourage rather than seek to prevent the formation of a blood clot in the wound. To avoid too great tension we may have at its upper portion small openings for the escape of superfluous blood, not at the lower portion, as for drainage. The line of the wound may then be covered with a strip of protective narrow enough to let the blood run out under its edges into the absorbent dressing. *The first dressing may remain from three to four weeks.* By this method Wolter has secured recovery of function in a remarkably short space of time.

The advantages of treatment without drainage are obvious, since nothing contributes in so high a degree to repair as perfect rest. This we can not have if we are constantly changing the dressing, as to change a drainage-tube, etc. Whether we are to attempt to have a blood clot form in our wound which shall be just large enough to nourish our granulations, and not large enough to cause tension, is another question. Wolter advises tying only the larger blood-vessels. It would seem to the writer that unless very firm pressure be applied this would allow the formation of too large a clot. The cases which are reported in this paper as sewed up without drainage—ten in number—have done uniformly well (except in two cases of infection and suppuration), so that as far as his observation goes the writer would urge a thorough hæmostasis, and suture without drainage.

With regard to the position in which the member should be dressed, it should manifestly be one which relaxes the tendon or tendons involved—i. e., of flexion for suture of flexors, and *vice versa*. It has been pointed out by Schüssler, and is a point worth noting, that if the hand is too completely flexed or extended under the dressing, we may interfere with the circulation in the wound or cause it to gape. In Case II of this paper it seemed to the writer that the forcible extension of the hand over a roller bandage interfered with the venous return of the back of the hand, and that the pressure of this roller directly over the wound caused the sloughing area through which it became infected.

After-treatment should be very judiciously and cautiously conducted. Passive motion should be begun as soon as possible, in order to free the tendon from the adhesions it has formed, but not before the cicatrix of the tendon has grown firm enough to stand the strain. It must be begun very gently, and the range of the manipulations and their force very gradually increased. We recall in this connection the rupture of the cicatrix of an extensor after four weeks, and of a flexor after seven, in Billroth's clinic; also the writer's case,* in which the cicatrix gave way in the third week, owing to too violent manipulation.

In general, it is unsafe to begin passive motion in the case of extensor tendons before the beginning of the third week, and in flexors before the fourth. According to Wol-

* Pitha and Billroth, ii, 910 ff.

* Case XIV.

ter, where the moist blood-clot method is pursued, these motions can be very rapidly increased and varied, for he reports cases of complete recovery of function in three to four weeks. In most cases, however, it will be better to wait six to eight weeks before carrying our motions to the full range.

When the operation is complicated by the fracture of bones, in the callus of which there is danger of the tendon becoming involved, passive motion must be carried out with especial care. That good results as to freedom of motion may be obtained even in these cases is shown by Cases V and VI of this paper.

In all these cases we should remember that it is not rare for improvement to be very gradual—say, six months or a year before complete recovery of function. Therefore the prognosis should not be necessarily bad if immediate recovery of function does not take place, but persistent treatment may attain good results even after a year or more.

(To be concluded.)

APPENDICITIS IN CHILDREN.*

By JOHN B. DEAVER, M.D.,

PROFESSOR OF SURGERY IN THE PHILADELPHIA POLYCLINIC
ASSISTANT PROFESSOR OF SURGICAL ANATOMY
IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA, ETC.

I HAVE selected the subject of Appendicitis in Children as my contribution before this Section for the following reasons: First, because the disease is one which occurs frequently in early life and, from some similarity of symptoms, is likely to be confused with and mistaken for some one of the various intestinal disturbances peculiar to children; second, because the gravity of the disease is such that upon its early recognition depend in a great degree the chances of recovery; third, because I desire to advocate the removal of the appendix in acute primary attacks as soon as the disease is recognized, where there has been no decided response to judicious medical treatment, and between attacks in all recurrent cases.

In a paper read before the last meeting of the American Surgical Association I maintained that all inflammations located in the right iliac fossa had their origin in the appendix, such a conclusion being the inevitable result of observations at both the operating and post-mortem table. I also proposed that the terms typhilitis, perityphlitis, and paratyphlitis should be expunged from the medical vocabulary as being misleading in their character and as presenting a classification which is anatomically unfounded and which clinically is incapable of demonstration.

I would therefore group under the term appendicitis all inflammatory conditions of the right iliac fossa, believing that in so doing a clearer conception will be formed of the true pathological conditions present, and that a common treatment—that of early operative interference—will be adopted universally.

All cases of appendicitis may be classified under the

following heads: Catarrhal, ulcerative, which may be the result of a circumscribed catarrhal inflammation or of an obstruction due to the presence of a foreign body, as a fecal concretion, an enterolith, a stricture, etc.; perforative, an advanced stage of the ulcerative type; tubercular; and relapsing or recurrent.

Pathological Changes.—The pathological changes occurring in cases of appendicitis vary according to the exciting cause, but are usually those common to inflammations of the intestinal tract and may present any of the conditions from a simple lymph exudate to a pus formation.

Ætiology.—Inflammation of the appendix may be the result of either predisposing or exciting causes. Among the predisposing causes age is an important factor, fifteen per cent. of all cases occurring under fifteen years. The youngest patient I have met with was a child two years old. Males are more prone to the disease than females are. A tubercular diathesis is not uncommonly the remote cause of a suppurative appendicitis. Chronic constipation is a further predisposing cause, which may induce either a catarrhal or an ulcerative type. Among the exciting causes may be mentioned the presence of seeds, enteroliths, fecal concretions, inspissated mucus, particles of undigested food, traumatism, and exposure to cold or dampness, but the most frequent exciting cause is the result of a previous attack.

History and Symptoms.—The onset is usually sudden, constipation the rule rather than the exception. We may be able to elicit a history of one or more previous attacks or of the rapid ingestion of some indigestible substance or overloading of the stomach.

The symptoms of appendicitis in its incipency are not by any means definite in all cases. The prominent and constant symptoms are pain, vomiting, and tenderness. The pain, which is at first paroxysmal, in this respect resembling colic, is referred to the umbilical and epigastric regions, and in seventy-two per cent. of all cases appears within twenty-four hours. Later it becomes continuous, and is localized in the right iliac fossa in fifty-four per cent. of all cases. Vomiting is present from the first, becoming uncontrollable if the case does not yield to treatment. The vomited matter consists first of the contents of the stomach, later of bile, and finally, if a plastic peritonitis supervenes by which the coils of intestine are immobilized from the resultant deposit of lymph, of stercoraceous matter in those cases in which the intestinal tract has not been emptied. Ordinarily the vomiting of stercoraceous matter is indicative of acute intestinal obstruction, yet we see stercoraceous vomiting in advanced and hopeless cases of appendicitis. The tongue is furred and later in the disease becomes dry with the deposit of sordes upon the teeth. There is extreme thirst, with a temperature varying from 102° to 104° F. and a high pulse rate. The bowels are usually confined; it is, however, not uncommon to have the disease ushered in with diarrhœa. The presence of sick stomach, diarrhœa, and pain coming on suddenly are suggestive of enteritis, the affection with which acute appendicitis in its incipency is most likely to

* Read before the Section in Diseases of Children of the Pan-American Medical Congress at its first meeting.

be confounded. As the affection advances, the child frequently favors the affected side and lies with the thigh of the corresponding side flexed upon the abdomen. Frequency of urination is often a prominent symptom, being due evidently to the involvement of the sympathetic nerves. Examination by palpation reveals general tenderness over the affected area, while the point of greatest intensity usually corresponds to the so-called McBurney point, providing the appendix occupies its most common position, arising from the postero-internal aspect of the base of the cæcum. I recall one case in particular where the greatest point of tenderness was immediately above the middle of Poupert's ligament. This, as demonstrated at the operation, corresponded to the angle of curve in the appendix, which arose from the postero-external aspect of the base of the cæcum and descended in front of the latter as far as its apex, where it curved abruptly upward. When general peritonitis is present early, as in the perforative variety of the disease, notwithstanding that there is a very general abdominal tenderness, yet, upon deep pressure, a point in the right iliac fossa corresponding to the appendix can be made out which is much more painful than any other point in the abdomen. Palpation also detects very decided resistance offered by the abdominal muscles of the affected side. In many cases an indurated mass is to be felt, which is circumscribed or diffused, particularly in the direction of the linea alba and of the pelvis. Superficial percussion in the early part of the disease yields negative information, while deep percussion, if the case steadily advances, will reveal dullness and later flatness. Deep rectal as well as vaginal examination I do not think of much diagnostic value, early in the disease at least. In those cases where the appendix projects into the pelvis it may be of some assistance. If a mass can be felt through the rectum or the vagina, palpation of the abdominal walls at the same time may elicit fluctuation. Suppuration is not always readily detected, as fluctuation is difficult to elicit on account of the unyielding abdominal wall. Yet I have seen it well pronounced many times. Œdema of the overlying abdominal walls is of great diagnostic value as indicating the presence of deep suppuration. If, associated with the presence of a mass in the right iliac fossa, there are decided chills, or even chilly sensations with sweating, it is quite evident that pus is present.

Diagnosis.—The establishment of a diagnosis depends on the character of the symptoms, the clearness of the history, the duration of the disease, and the previous treatment, as the administration of opiates to relieve distressing pain may mask many symptoms which would otherwise be prominent. The affections with which appendicitis is most likely to be confounded in children are enteritis, involving all the coats of the intestine (entero-peritonitis); acute mechanical intestinal obstruction; perinephritic abscess; abscess of the kidney, and especially so if the kidney be a floating one, as I have once observed; psoas abscess; iliac abscess; abscess of the abdominal parietes; hip disease; hepatic and renal colic. In enteritis involving all the coats of the intestine the disease is ushered in by a diarrhœa of a more or less severe type, in which the

stools are watery and mucoid in character. This is accompanied by pain of a colicky nature referred to that portion of the abdomen corresponding to the situation of the affected coils of intestine, also by the absence of abdominal distention. Later, however, when the muscular and serous coats are invaded by the inflammatory process, as a consequence of the infiltration and the involvement of the sympathetic nerve filaments supplying the coats of the bowel, paralysis of the bowel occurs which results in distention. Diarrhœa is now no longer present, but, on the contrary, absolute constipation with inability to pass flatus. Vomiting occurs which, if the disease is not relieved, becomes stercoraceous. Ordinarily there would be but little trouble in differentiating between this form of enteritis or entero-peritonitis and appendicitis if the symptomatology of the latter affection is borne in mind, in addition to what has been said about the physical signs elicited by careful abdominal palpation in cases of appendicitis.

In acute mechanical intestinal obstruction the two most common forms met with in children are invagination and strangulation by bands; the onset of the symptoms is more abrupt and severe than in appendicitis. In invagination, as in strangulation by bands, the pain, which is most intense and at first occurs in exacerbations, is referred to the seat of the obstruction, or more commonly to the umbilicus, and not concentrated in the right iliac fossa, as is the case in appendicitis when the disease is well established. There is absolute constipation with inability to pass flatus. Vomiting is an early symptom in both forms of obstruction, which, if not relieved, becomes stercoraceous. When peritonitis supervenes there is very little effort attending the vomiting. Properly speaking, the patient at this stage of the disease regurgitates fecal matter caused by the reversed peristalsis. There is absence of fever in strangulation by bands and in invagination unless the child survives until the invaginated portion of the bowel commences to undergo inflammation, which causes ulceration and affords Nature a means of disposing of the intussusceptum and thus establishing a spontaneous cure. In invagination the presence of a movable tumor, the most common site of which is to the left of the middle line, but not always to be made out on account of the distention, while in appendicitis a tumor, if present, is fixed and always occupies the right iliac fossa, are important differential points. In invagination a discharge of blood and mucus from the rectum, and in many instances the presence of a tumor, may be detected upon making a digital examination of the rectum. With the development of peritonitis in acute intestinal obstruction there is marked distention of the abdomen.

Collapse is an early symptom in acute intestinal obstruction, while not so in appendicitis unless it be of the perforative or fulminant variety; but even then it is a later manifestation than in obstruction. In perinephritic abscess the location of the swelling, the presence of œdema in the loin, and the absence of bowel symptoms, are important differential factors. In many cases of perinephritic abscess the trouble is preceded or accompanied by the presence of pus as well as other abnormalities in the urine.

This is not, however, true in those cases which have

their origin independent of the kidney, as when due to constipation, traumatism, etc. In perinephritic abscess, as in some cases of appendicitis, owing to the relation between the perinephritic tissue, the appendix, and the psoas magnus muscle, flexion of the thigh upon the abdomen is a symptom common to both affections. If a doubtful case should arise where it would seem to be impossible to differentiate, better than introducing an exploring needle or an aspirating needle, either of which procedures under these circumstances I regard as most unsurgical and attended by no little danger, I would advise an exploratory incision in the loin before cutting through the abdominal wall anteriorly; this could not possibly result in any harm, even if the perinephritic space be found intact; nor would it interfere in the least with immediately cutting down upon the appendix. In abscess of the kidney the same train of symptoms is largely present as in perinephritic abscess—namely, a mass in the loin corresponding to the position of the kidney, pus in the urine, history of renal colic, with perhaps the passage of small crystals of uric acid; yet to have renal colic it is not necessary that a stone or a fragment thereof should pass through the ureter, but simply a plug of fibrin or inspissated mucus, as I have seen upon several occasions in cases of pyelitis. In kidney abscess, nausea, with sometimes vomiting, is a not inconstant symptom. In the absence of urinary symptoms, abscess of the kidney, and particularly if it be one of a floating kidney, the differential diagnosis is necessarily more difficult. In the latter instance, however, the tumor will be movable—a point to be borne in mind. I have recently operated in the case of an acute suppuration of the kidney where the urine was normal and where the diagnosis was made purely upon the anatomical situation of the swelling.

In psoas abscess the onset is slow, with little or no fever, usually, though not always, accompanied by evidence of disease of the vertebrae, absence of pain, tenderness, and bowel symptoms.

There may be flexion of the thigh of the corresponding side due to the muscular irritation. What has been said of psoas is equally true of iliac abscess, if dependent upon bone disease. Should a collection of pus in the iliac fossa be dependent upon disease of the uterine appendages, a vaginal examination would reveal the cause. In the latter variety of abscess, however, the swelling usually holds a lower position than abscess the result of disease of the appendix, it being near Poupart's ligament—in fact, immediately above it.

Abscess of the Abdominal Wall.—Between abscess of the abdominal wall and that caused by appendicitis there should be but little difficulty in arriving at a correct conclusion. If the collection is in the superficial fascia it will be circumscribed, while if between the abdominal muscles it is likely to be diffused. The purely local character of the abdominal abscess, the swelling moving with the abdominal walls, the absence of intestinal symptoms, the presence of local and constitutional evidence of pus, coupled with the history of the case, should be enough to render a differential diagnosis possible.

Hip-joint Disease.—The presence of the characteristic

deformity, inability to execute the normal movements of the joint, pain referred to the knee, arching of the lumbar spine when the limb is brought into the fully extended position, absence of intestinal symptoms. If there is still doubt, the administration of an anæsthetic will suffice to dispel it.

Hepatic Colic.—In hepatic colic the painful area is usually higher in the abdomen, radiating toward the shoulder, most severe over the region of the gall bladder, and usually followed by jaundice.

Nephritic Colic.—In nephritic colic a history of previous attacks may often be obtained; the origin of the pain is deep in the upper loin, radiating in the line of the ureter, with retraction of the testicle, diminished urinary flow, with blood or pus, and a sudden termination of the attack. Retraction of the testicle may occur in appendicitis, due to irritation of the genito-crural nerve.

I recall a case of a physician in which the diagnosis of renal colic had been made, and in which the ureter was supposed to have been ruptured by the passage of a calculus. The autopsy revealed a gangrenous and perforated appendix with diffuse suppurative peritonitis.

Prognosis.—The age of the patient has a material effect upon the prognosis; the earlier in life it occurs, the less resisting power is exhibited by the patient. Sex does not seem to be a factor.

Where an abscess forms and ruptures or perforation takes place, and the contents of the bowel escape and are unconfined by a wall of lymph, general peritonitis is rapidly established, terminating these cases with a fatal uniformity. The most favorable point for spontaneous evacuation of the contents of an appendicular abscess is into the cæcum. Rupture into the rectum is also followed by recovery in the majority of cases. Rupture into the bladder is fatal in about fifty per cent. of the cases. The most favorable results have been recorded where early operative interference was instituted, the mortality under this plan of treatment being but six per cent.

Treatment.—Medical treatment: The first indication to be fulfilled in a case of appendicitis, or even of a supposed case, is to obtain a free action of the bowels. This is best accomplished by the administration of small and repeated doses of salines—preferably Rochelle salts—or, if the stomach is not tolerant to salines, small doses of calomel. The free evacuation of the bowels, not drastic purgation, serves the purpose of clearing the alimentary canal of all foreign and irritable substances—as particles of undigested food, etc.; relieves the congested blood-vessels, thus modifying the degree of the subsequent inflammation; and again fulfills a most important indication in having the bowels in the most favorable condition for operation in the event of its necessity. I can not emphasize this important part of the treatment too strongly, as upon it, I believe, largely depend the chances of the patient's recovery. Certainly, in my experience, the bulk of the cases I have seen recover without operation have been those where it was most thoroughly carried out, and in the cases operated upon the largest percentage of recoveries have been in those where the bowels were not allowed to be confined. Where there

is great pain, as we frequently see, in addition to the administration of salines or calomel, as the case may be, we may be forced to use an anodyne, and, if so, it should be given in the smallest possible dose.

The pain in appendicitis, which is colicky in nature, is due first to the muscular contraction of the appendix and the bowels, and in the majority of instances is provoked by irritation within both; therefore is not the evacuation of the intestines of their irritating contents urgently called for? Are they not, in other words, asking to be relieved? This being so, will not purgation take the place of an anodyne, as a hypodermic of morphine, which is so often and indiscreetly given? In other words, the best anodyne is the repeated dose of salts or calomel, which does more than any preparation of opium can do, both relieving and removing the cause of the pain. Recognizing the character of the pain, is it not possible to afford relief by hot applications to the abdomen in the shape of the hot-water bag, hot cloths, hot turpentine stupes, etc.? Internally, before giving opium, I prefer to use spirits of chloroform, carminatives, or extract of belladonna. If now relief is not obtained, then I administer a small dose of opium, and preferably by suppository, as I think we all agree that opium given in this form is less liable to cause sick stomach. Sick stomach is so frequently provoked by morphine given hypodermically that it is often difficult to say whether the nausea or vomiting is due to the morphine or to the disease. Further, there is no disputing the fact that opium or any of its preparations brings about a paretic condition of the bowel and thus favors distention, an obstacle difficult to contend with when endeavoring to elicit a mass.

If the case be catarrhal, the presence of congestion of the mucous lining of the appendix is the exciting factor in occasioning contraction of the muscular coat, which is the direct cause of the initiatory pain. Again, as has already been noted, emptying the bowels freely both removes an additional factor in exciting contraction of the muscular coat of the appendix, as well as depletes the circulation and renders the canal more patulous and better able to free itself of mucus, which, if retained, becomes inspissated.

The presence of inspissated mucous in catarrhal appendicitis is liable to lead to an ulcerative type of the disease. While I do not believe the good derived from purgation in the obstructive form of appendicitis is equal to that in the catarrhal type, yet I do not know of any other form of medication capable of accomplishing the same amount of good. There is some hope, too, in emptying the caecum that the orifice of the appendix may be rendered patulous and the expulsion of the foreign body facilitated. In the perforative and explosive or fulminant varieties of the disease, the latter being only a difference in degree of the former, active purgation would be ill advised on account of the fear of hastening and making greater the extravasation of fecal matter. The treatment by free evacuation of the bowels may be thought to be erroneous on account of the increased peristalsis resulting therefrom aggravating the already existing inflammation. The use of leeches and blisters is advocated by many in preference to purgation to accomplish depletion of the circulation. I must confess

this is not in accord with my experience. Blisters, I think, are particularly objectionable on account of the infiltration of the skin they occasion, which both interferes with palpation and the recognition of pus by the oedema of the abdominal walls.

The question of diet throughout the disease is important, and it should consist—until the patient is convalescing at least—of peptonized milk, koumyss, milk and Apollinaris or carbonated lithia water, liquid beef peptonoids, and concentrated beef tea, the latter being all the more indicated on account of its laxative effect. Buttermilk I find very grateful to many patients.

As to the propriety of the removal of the appendix in cases of recurrent appendicitis, there is, in my mind, no doubt. While I am willing to admit that my experience has taught me that acute attacks of recurrent appendicitis are less fatal than primary appendicitis, yet I can not see how this argues against removal of the appendix between attacks, the period for elective operation. I am unable to understand the philosophy of the argument that because a patient has survived a number of attacks of recurrent appendicitis, the appendix should not be taken out, since each recurring attack may possess elements of danger unknown to us which may deprive our patient of his life. Those of us who have observed these cases carefully know that many are the subjects of chronic invalidism. The percentage of mortality in operations for recurrent appendicitis in skilled hands is less than one per cent. The absence of inflammatory conditions so simplifies the operation that its after-conduct entitles it to be classed as a simple wound. This same absence of acute inflammatory condition which relieves the necessity for drainage and the consequent impairment of the integrity of the abdominal walls lessens in a great degree the liability to ventral hernia.

The after-treatment of these cases is so simple that it deserves special mention. It consists during the first three days of alimentation alone, absolutely no opiate, and at the expiration of this time, if the bowels have not moved voluntarily, of the administration of one-tenth-grain doses of calomel every hour or two until a desire to defecate is produced, when an enema is given.

Before discussing the operative treatment of this disease and while advocating the most radical methods, I desire to disclaim any intention of declaring that all cases where the ordinary medical treatment of the general practitioner has failed to afford relief are cases for immediate operation, as I believe that such a decision should rest only with an experienced surgeon, who may have carefully observed the progress of the case. Further, that the operation should be done by one who is thoroughly prepared to dispose of any of the unlooked-for conditions which are likely to be met with in any case. The skill required for the rapid and thorough performance of appendicial operations must be of the highest order, as time lost and prolonged etherization (by which the patient becomes, as it were, water-logged) during an operation may be just sufficient to turn to a fatal termination what would otherwise have been a successful result. This is of special importance when operating upon children, as we well know they do not bear pro-

longed etherization or operation. In the gravest types of the disease, when there is a sudden abatement of the symptoms, the attending medical man or surgeon, as may be, must not congratulate himself upon the rapid recovery of his patient and overlook the fact that this is a forerunner of perforation. On the contrary, if operation has not already been entertained, the strongest indication for its immediate performance now presents itself. Following this period (which is practically one of shock), in the course of a few hours—usually twenty-four—a general peritonitis has developed and the golden opportunity for offering the patient his only chance for relief is a thing of the past.

The technique of the operation for appendicitis where abscess exists varies by reason of the different local conditions found. When the abscess is circumscribed and shut off, after the pus has been evacuated and the cavity irrigated, if the appendix can not readily be found, it is not judicious to make a prolonged search for it, by which the limiting wall may be broken through and a communication with the general peritonæum established. In this class of cases, however, I have been fortunate enough in most cases to find the appendix and remove it without breaking through the abscess wall. This is always more satisfactory to the surgeon than to complete the operation by simply draining or packing the abscess cavity, and it removes what may be the cause of one or more attacks of the relapsing variety of the disease. When the abscess is in communication with the general peritoneal cavity a more prolonged search for the appendix may be made with less risk than in the preceding state, but the patient's general condition is usually so bad under these circumstances as to make it unwise to keep him under the effect of the anæsthetic any longer than is absolutely necessary.

The points I observe in making the incision for the removal of the appendix in acute cases where there is present a mass, be it pus or exudate, are the following: When the loin is rendered prominent by the mass or is the seat of œdema, I take it as an indication that the appendix holds a post-cæcal or an external antero-lateral position, or that it comes off from the apex of the cæcum, and I carry the incision parallel with and a short distance above the outer third of Poupart's ligament, prolonging it outward if necessary. When the mass presents itself well to the inner side of the anterior superior spine of the ilium, I carry the incision through the semilunar line—rather, through the rectus muscle immediately to the inner side of the semilunar line. The wound when carried through the muscle heals more solidly, and therefore there is less likelihood of the development of a ventral hernia than when made through the semilunar line.

In acute cases the treatment of the stump of the appendix will depend on its situation and the mobility of the cæcum; if the latter has become fixed through plastic adhesions, and it is not deemed advisable to make the manipulation necessary to bring it well up into the wound, the appendix is tied off *in situ*.

If, however, it is possible to present the appendix in a favorable situation, a circular incision is made through the serous coat half an inch from the cæcum, and the serous coat

then stripped back for the space of a quarter of an inch; the appendix is then tied off with fine silk, the serous covering replaced with edges inverted, and brought together with a Lembert suture. The latter disposition of the appendix is decidedly the most favorable, and is the method which we are enabled to employ in cases of recurrent appendicitis, with few exceptions. In cases of abscess of the pus cavity, when limited, is thoroughly irrigated and drained with either tubes or iodoform gauze, or both combined. When the peritoneal cavity has become generally involved, irrigation and drainage are employed in the usual way.

After-treatment.—The after-treatment in acute cases consists in the administration of small doses of salines repeated sufficiently often to free the bowels, with the same diet as before mentioned, alimentation being allowed immediately on cessation of other emesis.

120 SOUTH EIGHTEENTH STREET.

THE MEDICAL ASPECT OF DISEASED TEETH.

By A. HUGH HIPPLE, L. D. S., D. D. S.,

OMAHA, NEB.

THE development of what is known as the germ theory of disease has of late years directed the attention of physicians to the mouth as the point of infection to which the origin of many diseases might be traced, and has also called attention to the constitutional effects liable to arise from diseased teeth whose cavities are filled with pathogenic germs and whose roots are bathed in pus. The fact that dental caries is the most universal of all the diseases to which mankind is subject, and the painful nature of the complications which frequently arise from it, have caused it to receive some attention from medical writers; but, as a rule, dental lesions are regarded as trivial, the prognosis being exceedingly good so far as life is concerned, and as the loss of a tooth is too often looked upon as a matter of slight consequence, physicians rarely concern themselves very much about the teeth of their patients. The investigations of Dr. Miller, of Berlin, however, and of others, have shown that serious constitutional effects may arise and frequently do arise from diseased dental organs, and that death occasionally results from the absorption into the system of infectious matter collected about the root of a tooth. Ten cases of death from this cause were reported to Dr. Miller as having occurred in the Hamburg General Hospital, and from various sources he obtained the history of twenty-seven other cases that terminated fatally. In a number of other instances chronic pyæmia, the cause of which was obscure and which would not yield to ordinary treatment, disappeared at once upon the removal of a diseased tooth. The importance of diseases of the teeth from a medical standpoint being thus established, the writer, without discussing the local disturbances that commonly arise from dental lesions, desires to call attention to those more serious affections which result either from micro-organisms traceable to diseased teeth or from nervous irritation induced by the teeth.

A tooth in which caries penetrating the pulp cavity has caused the death of the pulp, its suppuration and the formation of an alveolar abscess can not but be regarded by the thoughtful physician as a menace to the general health and even to the life of a patient. "An examination of the skull will show a number of channels through which an inflammatory process in either jaw might reach the brain. The roots of the upper molars frequently pierce the floor of the antrum, from which the inflammatory process might extend to the nasal cavity, and through the cribriform plate of the ethmoid to the brain. If the inflammation extended to the back part of the mouth it might obtain entrance by way of the pterygoid fossa and the foramina at the base of the skull or by way of the inferior sphenoidal fissure and orbit. In the case of inflammatory processes in the lower jaw extending upward along the ramus, entrance to the cavity of the skull might be obtained either by way of the pterygoid fossa or the orbit. A case was reported in the *Dental Record* of July, 1888, of an abscess in the lower jaw of a boy seven years of age caused by carious molars, in which the inflammatory process extended to the orbit and finally resulted in abscess of the brain and death. In another case reported in the *Edinburgh Medical Journal* some years ago the inflammation first made its appearance at the roots of the upper teeth, from which it spread to the antrum. The ethmoid bone was next attacked and became carious, the inflammatory process finally reaching the brain, causing encephalitis and death.

Reference has been made to the cases mentioned by Dr. Miller, where a general infection of the blood from pus collected about the root of a tooth resulted fatally. Much more common, however, and more difficult to diagnose, are those cases of chronic pyæmia in which metastatic abscesses form in such parts of the body as possess, for the time at least, the least powers of resistance. That these may result from a diseased tooth is beyond a doubt, the virus from the seat of infection being carried to points more or less remote by the blood or lymph.

Empyema of the antrum of Highmore is a disease of frequent occurrence, and is the direct result of dental lesions in a very large proportion of cases. The roots of several teeth being separated from the cavity of the antrum by only a thin layer of bone, and in some cases actually penetrating it, the danger of an inflammatory process about the roots of teeth extending into it or of an alveolar abscess breaking through its floor is necessarily very great. Pus having collected within the cavity, its form is such that it can not be perfectly emptied without surgical interference, the opening into the nose being so high above the floor that more or less matter always remains. This naturally acts as an irritant, until finally the entire lining membrane becomes involved, resulting in a disease that is always loathsome, usually painful, and sometimes dangerous.

A serious inflammatory process, causing abscess and trismus, is often the result of an impacted wisdom tooth. There is some ground for believing that with the contraction of the jaws wisdom teeth are gradually disappearing from the mouths of civilized races, but in the vast majority

of cases these organs still persist, and in attempting to erupt into an already crowded dental arch frequently bring about a chronic state of irritation. Upon examining the mouth in these cases the third molar of the lower jaw is found crowded into the ramus, while the corresponding upper tooth occupies the extreme rear of the maxillary tuberosity. Some of the micro-organisms that are always present in the mouth, and that never seem to cause any trouble so long as the tissues are in a perfectly healthy condition, soon find their way into the space between the crown of the partially erupted tooth and the gum covering it, and following the roots into the jaw, where the resistance of the tissue is diminished as the result of long-continued irritation, bring about a series of disturbances that occasionally end in necrosis, or even death from septicæmia. These cases are of particular interest to the physician, as the lesion is liable to be referred to some other cause, the presence of a wisdom tooth being often unknown to the patient, and the swelling and trismus making examination of the mouth almost impossible.

Just what effect upon the stomach is produced by the constant swallowing of bacteria and pus from diseased teeth, mingled with decomposing particles of food, we are unable to determine, but it is reasonable to suppose that gastric disturbances are greatly aggravated if not induced by so doing. In every community there are those who are enthusiasts on the subject of pure air and wholesome food, but whose mouths are in such a neglected condition that the air which passes through them is almost as polluted as that of a crowded tenement, and every mouthful of food swallowed carries with it into the stomach millions of bacteria. The almost entire futility of sterilizing articles of diet for patients in whose mouth chronic abscesses exist, or whose teeth are covered with tartar mixed with mucus and food in a state of decomposition, need hardly be mentioned.

Of the more uncommon infectious diseases which have been traced to the action of mouth bacteria, and in the introduction of which into the system diseased teeth have been found to play a part, actinomycosis is one of the most interesting. This disease, which is widespread among cattle, was first described in man by James Israel, and is caused by a ray fungus that usually enters the body through the mouth. It gives rise to a small granulation tumor, followed by extensive proliferation of the adjacent connective tissue, forming a growth which, in the jaw, is easily mistaken for osteosarcoma. The lungs are frequently affected, and Osler says that thirty-four such cases have been reported since 1878, all but two of which proved fatal. A very interesting case, observed by Israel and described by Dr. Miller in the *Dental Cosmos* of February, 1891, was that of a driver, aged twenty-six, who was in the habit of sleeping in his barn, and frequently drank out of the same trough with his horse. The left side of the man's breast was covered with abscesses and ulcers, but the primary seat of infection was not discovered until after his death. The autopsy revealed an actinomycotic cavern in the anterior portion of the superior lobe of the left lung, in which was an irregular calcareous body about the size of a No. 6 shot.

This was sent to Dr. Miller for microscopic examination and proved to be a small fragment of dentine surrounded by phosphate and carbonate of lime, incorporated with which were numerous threads of the ray fungus. There seemed to be no doubt that the fragment was the carrier of the infection.

A very interesting field for investigation, and one that has as yet been imperfectly explored, is the influence of the teeth in inducing reflex nervous disorders in other parts of the body. The anatomical relations of the teeth are well known and their nervous connections have been carefully figured out, but while our knowledge in these directions may show us how reflex disturbances of the eye, ear, and other organs are possible as the result of dental lesions, many of these phenomena must, with our present knowledge of the subject, be regarded as mysterious.

That there is an intimate relation between ocular disorders and pathological conditions of the teeth is shown conclusively by Dr. Brubaker in the *American System of Dentistry*. He prefaces his remarks, however, with the statement that at the time of writing ophthalmologists were hardly prepared to admit that such disorders could result from dental irritation, Graefe and Saemisch merely alluding to such a relation, and Stelwag and Wells omitting its mention entirely. He adduces a large number of cases in support of his position that reflex ocular disturbances are frequently induced by the teeth, some of which are quite startling. One of the most remarkable was a case of amaurosis extending over a period of twelve years, which was cured within a few days by the extraction of a tooth. In a paper read before the New York Odontological Society in 1891, Dr. Stevens referred to the recent utterances of Galezowski upon this subject. This distinguished oculist says that many rebellious cases of corneal disease arise from reflex irritation induced by difficult first dentition; that neuralgic affections about the eyes are often due to the second dentition; and that the appearance of the wisdom teeth is frequently associated with other ocular disturbances. Dental caries, he believes, is responsible for many cases of accommodative asthenopia, and he relates a case of blindness of one eye, where no lesion could be detected with the ophthalmoscope, which he attributed to the extraction of a tooth. Tomes says that "many well-authenticated cases have been recorded in which not only functional but organic diseases of the eye have been distinctly traced to the presence of diseased teeth," and mentions the case of an adult who had strabismus for three years, and ptosis for a portion of that time, both of which were completely cured by the extraction of decayed teeth.

Oral irritation appears to be much less frequently referred to the ear than to the eye, although in some cases aural derangements undoubtedly owe their origin or continuance to diseased teeth. Magitot says that partial or total deafness is sometimes the result of dental caries, and Vautier tells of a case of deafness that resulted from a diseased wisdom tooth. Robert Barclay has reported twenty cases of various aural derangements which were not benefited until thorough dental treatment had been instituted. He believes that as the result of oral irritation reflected to

the ear a change is produced in the caliber of the blood-vessels, through vaso-motor influence, which is followed by hyperemia, increased glandular activity, and congestion of the integument of the canal and mucous membrane of the tympanum. In a lecture to the students of Guy's Hospital, some years ago, Dr. Hilton gave a detailed statement of the case of a professional friend, Dr. Addison, bearing upon this point. The patient had suffered for some time from a very offensive discharge from the auditory canal of one of his ears, and below the external ear was an enlarged gland. Aural treatment had been tried without success, until a diseased lower molar was diagnosed as the probable cause of the trouble. This was extracted, after which the discharge and morbid secretion soon disappeared and the enlarged gland subsided. Dr. Hilton was of the opinion that the dental irritation was conveyed to the auditory canal and induced a morbid secretion. This morbid secretion led to an ulceration, and the fluid from the ulcer being absorbed by the lymphatics and carried to the gland, caused its enlargement. Josef Gruber tells of a boy thirteen years of age who showed symptoms of fright and complained of a very disagreeable sensation in both ears whenever he heard the slightest unexpected sound. This increased sensibility disappeared upon the extraction of a decayed and painful tooth.

Cases of epilepsy and paralysis caused by carious teeth have been reported, but might reasonably be discredited were it not that they have been recorded by observers whose veracity and ability in diagnosis are unquestioned. The famous Dr. Benjamin Rush, of Philadelphia, in a letter to Dr. Miller, written in the year 1802, tells of a case of epilepsy in his practice that was cured by the extraction of several decayed upper teeth, and a similar case is quoted by Tomes as having been reported by Dr. Ramskill in the *Medical Times and Gazette*. In *Guy's Hospital Reports* for 1868 is the record of a woman who had suffered for two years from severe pains in the face, neck, and left arm. Nearly all muscular power in the arm had been lost and she was unable to raise it to her head. The extraction of a lower wisdom tooth gave immediate relief, and all the symptoms disappeared within a very short time. A lower wisdom tooth was also the cause of paralysis of the arm in the case of a woman, twenty-four years of age, reported by Salter, and reports of similar cases have from time to time been published.

But perhaps the most common and certainly the most painful reflex disturbance liable to arise from diseased teeth is facial neuralgia. Given a patient with the neuralgic diathesis, and the most trivial dental lesion seems sufficient to bring on an attack of this malady. Indeed, patients who do not appear to possess more than an ordinary susceptibility to reflex or sympathetic disturbances frequently suffer from severe neuralgic pains as the result of apparently trifling dental irritation. Dr. Garretson tells of a surgeon of the United States navy who came home from China under the impression that he had softening of the brain. He was suffering severely, and had consulted many physicians that he had met abroad, but had received no benefit from their treatment. Upon examining the mouth, Dr. Garret-

son found an upper bicuspid tooth with one of the most beautiful fillings in it that he had ever seen. At a venture he extracted the tooth, and thereby effected an instantaneous cure. Some time ago the writer was consulted by an apparently healthy old gentleman, who stated that he was suffering from *tic douloureux*. He had been treated by prominent physicians in various cities without obtaining relief, and had given up all hope of a permanent cure. Life had become a burden to him, however, and as the extraction of a couple of sound teeth had given him temporary relief upon a former occasion, he was considering the advisability of sacrificing his teeth one by one. None of them were carious or tender to percussion, but, upon making a careful examination of the gums, a minute opening was found, just back of the right upper cuspid, that appeared to lead upward to the fragment of a bicuspid root. There was no swelling, no tenderness, no pus, but extraction was advised, and afforded prompt and permanent relief from all the symptoms.

In concluding this article—which, by the way, is intended to be merely suggestive—the writer feels that he can not do better than quote from the letter of Dr. Rush, before referred to:

I can not help thinking that our success in the treatment of all chronic diseases would be much promoted by directing our inquiries into the state of the teeth of sick people, and by advising their extraction in every case in which they are diseased. It is not necessary that they should be attended with pain to produce disease, for splinters, tumors, and other irritants often bring on disease and death when they give no pain and are unsuspected as the cause of them. The translation of sensation and motion to parts remote from the place where impressions are made appears in many instances, and seems to depend upon an original law of the animal economy.

Fortunately, we no longer find it necessary to extract all decayed teeth; but the necessity for making a thorough examination of the mouth in cases of chronic disease is as great now as it was then, and, with the extension of our knowledge, our ability to relieve suffering has greatly increased.

311 BROWN BLOCK.

LUPUS, ITS EXTIRPATION.

WITH REPORTS OF CASES.*

By B. MERRILL RICKETTS, M. D.,

CINCINNATI.

So much has been said about this disease during the last three years by men who have spent the greater part of their time not only in treating it, but in studying its pathology, that it might seem preposterous for one with limited advantages to offer anything new whatever concerning this much-dreaded disease. The ravages that it produces and its persistent character have made not only the sufferer but the surgeon desperate. Considered in the light of experience, it is not strange that the treatment of to-day gives

but little relief. Koch has perhaps more nearly approached a panacea for lupus than any other investigator. Whether or not the future treatment and consequent good results are to be obtained by following up his principles is yet a question. That the disease is both local and constitutional there seems to be no doubt, and when a lesion is cured the preponderance of evidence is that it was a mistaken diagnosis; that it was not lupus, but some other disease of less virulency. However this may be, we must necessarily depend, to a great degree, upon the clinical history and appearance of the lesion. While we depend upon the microscopical investigation, we must not accept the picture as one to be recognized at all times. While I believe that the bacilli when found indicate a certain disease, I can not accept a statement that it is not that disease because the bacilli can not be found. In other words, I am not ready to accept the microscopical investigation as infallible. I would rather depend upon the clinical history and appearance in making a diagnosis of lupus than the statement of any microscopist. Neither do I believe in the infallibility of any diagnostician. Anything may be deceptive; just so may a person be deceived. The rarity of the disease and the few cases which the average practitioner has the opportunity of seeing, especially outside of the larger cities, is no doubt the occasion of mistaken diagnoses. It is not supposed that a man who sees a great many cases of disease is as likely to be mistaken in his diagnosis as one who sees but few. Consequently we must rely mostly upon the statement of those with greatest experience, especially in distinguishing lupus from other diseases. My experience has been somewhat limited—I have seen in clinical and private practice about sixty-five cases—but I was early convinced that treatment of any kind availed but little. This naturally led me to resort to more desperate means than were usually employed by those with whom I was associated. Scarification, curetting, cauterization in the various ways, the application of caustics, such as nitrate of silver, carbolic acid, etc., all convinced me that the disease, when possible, should be excised or that constitutional treatment was necessary. Constitutional treatment having been found useless, left to my mind nothing but total extirpation. Unfortunately, the disease occurs mostly about the face, eyelids, nose, ears, and lips—places where extirpation is made with the greatest difficulty, and where the greatest deformity is the result. I believe that the extirpation of lupus is about as certain, when done in its earliest stages, as some of the forms of epithelioma and sarcoma. The question arises, When does it become constitutional, and to what degree may it become constitutional when extirpation would be useless? It is also important to determine that degree in any of the malignant growths. If lupus is found upon the finger, we would not hesitate to amputate it; if lupus were to appear upon the hand, we would naturally resort to all means of treatment to save the hand. Would it not be better to remove the hand early in the progress of the disease? We know that the removal of a finger affected with lupus has cut short the disease, and that the patient has lived for years without any recurrence. Now, if this is so, why is it not rational surgery to extirpate any

* Read before the Dermatological Section of the First Pan-American Medical Congress, held in Washington, D. C., September 5, 6, 7, and 8, 1893.

diseased lesion that may appear upon any part of the body? The means that we now have at our command in restoring parts with both single and double pedunculated grafts should encourage both the operator and the patient in resorting to early surgical interference, no difference upon what part of the face the disease may be found. The dread of suffering, taking an anæsthetic, and being deformed, I might say, is the occasion of so much procrastination, not only in the treatment of lupus, but all other diseases. What are we to do with these unfortunate creatures when they present themselves to us for treatment? Are we to tell them that nothing can be done, that it is folly to attempt to relieve them? Believing, as I do, that all diseased tissue should be removed when possible, I have been led to extirpate lupus on several occasions with most gratifying results. So far I have not made any classification of the disease. It is, however, necessary in order that we may talk more intelligibly and simplify matters. I have treated the two forms of lupus in the same manner.

1. Lupus vulgaris.

2. Lupus erythematosus.

Of the former I have seen forty-two cases; of the latter, twenty-three.

CASE I.—Female, aged sixty-seven years, single, white, American, poorly nourished, posterior spinal curvature, most excellent habits. There had existed for about eighteen years a lesion upon the left cheek on a line with the lower edge of the ear. This was red and had gradually increased in size, with here and there a tubercular nodule, giving all the characteristics of lupus vulgaris. There were also cicatrices in the surrounding tissue, showing that some of them had at various times healed and given place to more recent ones. She consulted me to see if something could not be done. My diagnosis being that of lupus vulgaris, I offered no suggestions other than the total extirpation of the diseased tissue. This she readily consented to, and under the influence of cocaine, subcutaneously, I removed what I believed to be the entire amount of tissue involved. Union was primary, and she was discharged at the end of five days. Within the course of six months it was evident that the disease had not been entirely removed, and I again excised it under the influence of cocaine, with the same good results, so far as healing was concerned. She was discharged at the end of six days, and we again felt that we had done all that was necessary to rid her of the annoyance. At the end of twelve months the disease again manifested itself, and I concluded to excise it as before under the influence of cocaine, curetting the surface thoroughly, and applying arsenious acid in combination with cinnabar. This was done, and an extensive sloughing was the result. It required several weeks for the wound to heal by granulation, her health in the mean time being somewhat impaired. However, by judicious management and her ability to take the requisite amount of food, her recovery was uninterrupted, and she was discharged at the end of eight weeks. There was no family history of tuberculosis in this case. The spinal curvature was attributed to an injury. However, I am inclined to believe that the subject was a tubercular one without any special manifestations.

She died three years after from an attack of acute gastritis, the lupus never having manifested itself again in the slightest degree.

I report this case to show the importance of persistency in the treatment not only of epithelioma and other malign-

nant growths, but that of lupus in any form. What the result would have been at the end of ten or fifteen years, had she lived, I am, of course, unable to say.

CASE II.—Female, aged seventy years, widow, white, German, in a most excellent state of health, consulted me in January, 1889, for a small lesion upon the margin of the right nasal ala, which had existed for eight years. The disease had been slow in progress, giving her no special discomfort or annoyance. It had, however, made inroads upon the wing, involving a surface about half an inch along the lower margin, extending about three eighths of an inch upward along the side of the nose. My diagnosis was lupus vulgaris, and my suggestion was its total extirpation. This was consented to, and the operation made under the influence of cocaine, subcutaneously. A sliding flap was taken from the cheek and placed in the intervening space, allowing the lower margin of both remaining pieces of the ala to form the lower margin of the wing. Primary union was the result, and the patient is to-day entirely free from the disease. This has now been fifty-four months. Possibly there may yet be a recurrence, but has not the result proved that the operation was justified? There was no indication of tuberculosis in this case, nor was there any history of its having existed in her family.

CASE III.—Male, aged forty-eight years, white, Irish, excellent health, weighing about one hundred and sixty-five pounds, laborer, irregular and dissipated habits. He consulted me in July, 1887, for a lesion upon the left side of the nose, about midway between the inner canthus and lower margin of the ala, which had existed for eleven years. The disease had been slow in its development, and there was no special discomfort or pain. It gave all the characteristics of lupus vulgaris. I advised its total extirpation, and made the operation on the following day, under the influence of cocaine, subcutaneously. I removed a piece of integument about an inch wide and an inch and a half long, cutting through the cartilage into the nasal cavity. A sliding flap was made, filling the space perfectly, and resulting in primary union. This has never recurred, and I feel sure the man is as exempt from a recurrence of this disease as if it had been epithelioma. He did not give any history of tuberculosis, except on the father's side, in which case the patient's own uncle died from what was considered consumption following pneumonia.

CASE IV.—Female, aged sixty-three years, single, white, American, in good health, weighing one hundred and twenty pounds, consulted me in 1890 for a lesion upon the left cheek just in front of the ear, covering a surface about an inch and a half in diameter. This answered the description of erythematous lupus, and it was so classified. It had existed about twelve years, without giving any pain or discomfort except a burning sensation, itching, and extensive exfoliation of the cuticle. It had gradually become larger, and caused considerable anxiety on the part of the patient and her friends. Extirpation was suggested and readily consented to. This was done after thoroughly anæsthetizing the field of operation with subcutaneous injections of cocaine. The edges of the wound were coaptated with silk sutures, and primary union secured. I cut in this, as in all the other cases, far beyond the line of demarcation, and removed the entire integument and cellular tissue overlying the muscular structures. There has not in this case been any return.

This is the only case of erythematous lupus in which I have been able to do the operation of extirpation, and I am quite sure that I would earnestly advise such a course, although my experience is limited to one case. True,

where the disease has been allowed to progress to an extensive degree over the cheeks or about the eyelids and lips, or nose, or ears—in other words, where the disease has been allowed to extend to such a degree that extirpation would cause great deformity, which could not be prevented or overcome by grafting—one must necessarily hesitate in resorting to such radical measures.

In conclusion, I wish to say that I would not hesitate to extirpate lupus tissue in any case where the parts may be restored in any way whatever. Neither would I hesitate to amputate a finger or toe upon which either one or the two forms of lupus existed. There are cases, however, where it might be unwise to extirpate the lesion. Even in cases of multiple lupus I would advise their excision if the areas affected are small. Whether this plan of treatment should be limited is a question with the operator. So far, I have seen but three or four cases of multiple lupus. I am quite sure that in each case good would have resulted from the extirpation of the lesion which either one of them possessed. Would it not be well for us to draw a halt in saying that there is nothing to be done in cases of lupus? I believe that the pendulum should be swung in the opposite direction, and that the preponderance of evidence at the present time fully justifies this statement. Even though the disease should recur, it is not until quite a length of time has elapsed. I believe that the end justifies the means, and that it is humane to subject these unfortunate patients to the operation of extirpation, even though the relief be but for a short time. This, of course, requires more judgment in cases of lupus upon the various parts of the face. I have presented the subject to see if it can not be brought more prominently before the surgeons—that is, the operation of extirpation. I think that the cases I have reported, and the subsequent good results from extirpation, fully substantiate what I have said. Possibly I am deceived in my diagnosis, but I am thoroughly convinced in my own mind that I am not. I do not mean to be understood as saying that the disease will not recur in either one or all of the cases; surely I could not be so foolish as to say that. I propose to extirpate lupus, if possible, wherever found. I believe if this is done that a great deal of suffering, disfiguration, and I might say loss of life, will be prevented.

It would give me great pleasure if those who have been interested in this procedure would address me upon the subject. By doing this, I hope to tabulate the various cases in which the operation has been resorted to.

"THE TRINIDAD," 137 BROADWAY.

LOCAL ANÆSTHESIA BY ETHYL CHLORIDE.

By C. L. GIBSON, M. D.

ETHYL chloride is one of the newest local anæsthetics suggested. My experience leads me to believe that it is destined to occupy a useful place among our local therapeutic agents.

There are several preparations made by various firms, and, as far as I have observed, of equal merit. The prepa-

ration which I have used is that made by Dr. Bengué, of Paris. Its properties are thus described by the maker: "Ethyl chloridé is a colorless liquid, with a slight ethereal odor of an agreeable character. The density is 0.874 at 41° F.; it boils at 52° F.; its vapor density is 2.219. Ethyl chloride is very inflammable, burning with a green-edged flame and setting free hydrochloric acid."

The anæsthetic comes in glass bulbs of the capacity of a little over an ounce. The bulbs are provided with a capillary orifice, upon which a tightly-fitting cap is screwed, preventing evaporation. One bulb furnishes sufficient anæsthesia for six to eight minor procedures. In using this agent, the cap is first unscrewed and the bulb held in the palm of the hand, when the liquid will be instantly volatilized by the heat of the body. The bulb should be held horizontally and six to eight inches from the part, playing the stream back and forth as evaporation is produced. At first a hyperæmia results, then pallor, and gradually the part assumes a parchment-like appearance. From one to two minutes is needed, and anæsthesia lasts as long again.

My experience with ethyl chloride comprises some twenty-five cases of minor surgery, chiefly cellulitis of the fingers, abscesses of the jaw, buboes, sinuses, boils, and carbuncles. Most of the cases were relieved by a single incision, and in such the anæsthesia was most satisfactory. Where more extensive procedures were demanded, where deeper structures were divided, for efficient curetting, etc., the agent was seldom efficient.

Its action in certain cases, however, was ideal. In felons, for instance, the single rapid incision was generally effected absolutely without pain. Every one that is called upon to incise felons knows how excruciating the pain is. The patient winces at the slightest touch; the introduction of cocaine solutions subcutaneously is almost a cruelty, as intense pain results both from the needle pricks and from increase of the tension in the indurated tissues. Moreover, the cocaine often proves powerless to overcome the aggravated conditions. It is especially in such conditions that I believe chloride of ethyl will prove invaluable.

No attempts to use ethyl chloride were made in procedures requiring more than a few seconds' time, nor where careful dissection was needed, as the agent so changes the character of the tissues. It can, however, be employed to great advantage in removing small sections of tumors for microscopical examinations.

It will occasionally be found useful to combine the action of the new agent with that of cocaine.

I had recently to operate for ingrowing toenail on a young child. When I made the first prick of the needle, in order to cocaineize the parts for Anger's operation, the little patient grew so obstreperous that I could do nothing with her. I laid down the syringe and sprayed the proposed line of insertion of the needle with the chloride of ethyl, obtaining enough anæsthesia to allow the introduction of the needle without attracting the child's attention, and the battle was won in favor of the operation.

The ethyl chloride will be found of considerable value in dermatological practice, especially for thorough scarification and application of the actual cautery. Dr. Bengué's

bulbs intended for dental surgery are provided with curved nozzles, allowing the spray to be deposited on the desired spot. I have had no opportunity to verify the use of this agent in such work. The following are Dr. Bengué's directions:

"In extracting teeth the jet should be directed to the dental nerves, as near their origin as possible; in front of the ear for the upper teeth, behind the angle of the inferior maxilla for the lower ones. The spray should be applied for about a minute; but the anæsthesia thus produced is not so complete as when the jet is applied directly to the gums, and, as this last method is devoid of danger, its use is advised in all cases except those of the last molars, which are not easily reached by the spray."

Differing from the usual action of these agents, which act by refrigeration, I have never observed any bad after-effects, such as great pain or sloughing of the tissues. Care should be taken that the jet is not brought into contact with a light or incandescent surface, as the substance is highly inflammable. The eye should be protected from the spray. General symptoms of poisoning may be produced by inhalation, according to Crocker.

My attention was first called to the value of ethyl chloride as an analgesic by its success in the hands of a French gentleman in the treatment of a severe intercostal neuralgia. I have had very little occasion to use it for such purposes, but it has certainly proved very efficient in treating the pain of a supra-orbital and occipital neuralgia. The jet was played over the painful point for a few seconds at a time, being repeated at short intervals on recurrence of the pain without the slightest bad after-effect. Dr. Bengué suggests the use of chloride of ethyl in a very extensive class of cases, among which I will mention all the forms of neuralgia and rheumatic pains, various hyperæsthetic and reflex conditions, and the various forms of colic.

The chloride of methyl, as far as I have witnessed its action in the hands of others, is identical in results with chloride of ethyl. It is less convenient to use than the preparation with which I have experimented, as it is contained in little bulbs whose capillary end must be broken off before use, thus necessitating the employing of the entire contents at one sitting. A rough estimate of the cost of the ethyl chloride, as I have used it, is ten cents for each surgical anæsthesia.

46 WEST THIRTY-THIRD STREET.

The Death of Dr. Edwin N. Colt, of Brooklyn, occurred on the 15th inst. He was in his eighty-third year, and was born at Hinsdale, Massachusetts. He obtained his medical degree, when twenty-two years old, at the Berkshire Medical Institution. Sixty years ago he took up his residence in Williamsburgh, now a part of the city of Brooklyn. At that time the village of Williamsburgh was estimated to have a population of five hundred souls. In 1891 Dr. Colt was tendered a complimentary banquet in honor of his eightieth birthday and of his long-continued professional activity in the community that had grown up around him.

The Death of Dr. William B. Towles, of Charlotte, Va., professor of anatomy in the University of Virginia and in the University of Vermont, took place on Monday, the 18th inst. Professor Towles was one of the most popular and effective lecturers on anatomy in the country. He was fifty-three years old.

THE HYGIENIC AND PHYSIOLOGICAL PROPERTIES OF
ALCOHOL.

THE *Medical Week* for September 1st contains a *résumé* of some papers read before the fourth International Congress against the Abuse of Alcoholic Liquors, held at the Hague on August 16th. Sir Dyce Duckworth expressed the opinion that from a scientific point of view the use of alcohol could not be regarded as injurious to health. On the contrary, owing to its nutritious properties, it was likely to be of signal service in many cases. No legislation of any kind would ever succeed in suppressing its consumption, and, even were such suppression possible, the advisability of such a proceeding would still have to be proved. It had not been demonstrated that the use of alcohol was injurious to the nations of Europe, for the most highly civilized nations made use of alcoholic liquors. There was no evidence that the simultaneous use of alcohol and good food was injurious to the human body, while for certain people complete and continual abstinence from alcohol was not to be recommended. It was not to be denied that the offspring of alcoholic or neurotic parents should abstain from alcohol, or that the use of impure and adulterated alcoholic liquors was attended by serious risks to health. Total abstinence had nowhere succeeded in bringing about the disappearance of intemperance, and the young should be taught to recognize the difference between the legitimate use and the abuse of alcohol, and to moderate their appetite for that article.

Dr. Schmitz, of Bonn, agreed in many respects with Sir Dyce Duckworth's opinions. He did not believe that alcoholic liquors were essential to the preservation of good health, though the moderate use of alcohol was not injurious to health and even exerted a favorable influence on certain physiological functions. But the abuse of alcohol was dangerous, even for healthy individuals, and was positively fatal for those of a nervous constitution. He also considered alcohol a valuable, and in some cases an indispensable, remedy in disease.

Professor Forel, of Zurich, dissented from this latter opinion, and declined to admit that alcohol had any therapeutic value whatever. In his opinion, the favorable effects observed after its administration in certain cases were the result of mental suggestion by the medical attendant. This opinion was sustained by Dr. Pearse, of London, who protested against Sir Dyce Duckworth's and Dr. Schmitz's opinions.

It can not be said that this congress has done much to further the solution of the problem regarding the utility of alcohol. Sectarianism seems to be as influential in creating opinion in this matter as it has been in other things medical, though

it must be acknowledged that it is remarkable that the majority of physicians should continue the employment of an agent that did not afford satisfactory evidence of beneficial effect. As the punster said: If St. Paul thought a little wine was good for the stomach's sake, why should not the physician believe it good for the stomach's ache?

THE CHINESE PRACTICE OF FOOT-BINDING.

In the June number of the *China Medical Missionary Journal* there is an interesting article on this subject, by Dr. Marie Haslep, of Shanghai, with an editorial foot-note giving citations from an article by Dr. Faber. It seems that Chinese writers disagree as to the origin of the practice, but it is thought to be certain that it originated in an Imperial harem during the T'ang dynasty, about 1,400 years after the time of Confucius. It is said to have been resorted to to disguise natural deformity. It is illegal, because the emperor's will is the country's law, and the emperors of the present dynasty have publicly prohibited it. It is also contrary to Imperial example, for the Empress of China, the highest ladies of the court, and all Manchu ladies allow their feet to grow in their natural form and to their normal size.

According to Dr. Haslep, the ordinary manner of binding the feet is as follows:

While the great toe is left straight, the other toes are folded on the plantar surface of the foot, often until the tips of the toes are on a line with the edge of the inner side of the foot, and then the foot is bound "snugly." Gradually the bandage is made tighter and tighter. When the metatarsal bones begin to curve, making the characteristic lump on the dorsum of the foot, the bandages are tightened more rapidly than before. If swelling takes place above the ankle, the foot is bandaged more tightly. If ulceration occurs, the foot is bandaged tighter. Swelling is not a desirable complication. Ulceration is greeted with joy, for it is usually a sign that the foot is yielding gracefully to the inevitable. "*Lan siar kiäh*" (ulcer, small foot) is a common saying. To make the smallest foot, with the minimum of suffering and produce no untoward results, is the desideratum; this process should take about ten years. Patience will then show her perfect work; that which foreigners call a deformity and restricted locomotion are necessary sequels, not untoward results. This is the method ordinarily practiced. But there are careless persons, or cruel, who, having neglected to begin to bandage the feet of a child at the proper time (which is when she is between three and five years of age), or having bought a child with unbound feet, desire to accomplish the same end in a shorter time. In these cases the feet are bandaged tightly and smaller from the first. The work is sometimes done by a relation or friend, ignorant of the risks taken by so doing, or ignoring them. Oftener the services of a professional bandager are obtained. This woman carries with her a stock of small wooden shoes of various sizes. These are the patterns. Her patrons choose the size desired. A contract is then made to have the foot of this size in a certain length of

time—three years or more or less as the case may be. The shorter the time, the harder for the child, especially if she is one of the neglected ones whose feet have been left to Nature more years than is well, if they can not be left with her for all time. The professional bandagers, for the most part, fulfill their contracts with superb indifference to the children's sufferings, and sometimes with such results as the death of the child: gangrene of the feet, necrosis of bones, etc. In any case, says Dr. Haslep, with the predisposing element of impeded circulation, freezing or burning, both common casualties, will excite trouble more readily than in the natural foot. What shall be done, she asks, to stop this cruel practice? To her there appears but one true way, and she thinks it is also sure. Educate the heads and hearts, she says, and let these educated heads and hearts care for the feet. This will take many a year, and, judging from the history of its analogue in the West, China may become a Christian nation, may take her stand among the foremost nations of the world, may even, as some prophesy, lead all other nations, and her women hold a position above that of even the most envied women of to-day before the era in which all feet will be of natural size arrives.

MINOR PARAGRAPHS.

THE DEATH OF STANLEY'S FAVORITE SURGEON.

SURGEON T. H. PARKE, of the Emin Pasha Relief Expedition, commanded by Stanley, died suddenly last Sunday. He was on a visit to the Duke of St. Albans, at Alta Craig, when his sudden and fatal illness came on. Dr. Parke's relations with the great explorer on the heroic march across the Dark Continent were of the most intimate and confidential nature. He was unselfish and devoted to the men in his detachment—for he was a captain as well as a surgeon—to a degree that has won the admiration of all who have read the narrative of Stanley, of his marches and countermarches in Darkest Africa. Stanley speaks of him as "the good surgeon" and "our priceless doctor," and says no case of injury or disease could be so offensive or repugnant to the senses as to rob it of its interest to the surgeon in charge. When Parke was himself broken down by fever, and unable to go to the bedside of his comrades without support, he would have his men carry him and his medicine chest to where the sick men lay. In fact, there was probably no exaggeration in Stanley's ante-mortem epitaph, which recites that "his devotion was as perfect as human nature is capable of rendering." On his return home to England, Parke was made the recipient of many honors by the profession in London and Dublin and by the Royal College of Surgeons of Ireland. The Government also, although somewhat tardily, recognized the worth and services of this soldierly surgeon by giving him a desirable promotion in the army medical staff. He was about forty years of age.

THE FIRST INTERNATIONAL SAMARITAN CONGRESS AT VIENNA.

This congress has held its first meeting in Vienna under favorable auspices and with good results. Dr. von Esmarch, of Kiel, has been largely instrumental in the formation of this organization, as well as in the establishment at Berlin and Vienna of the two chief local Samaritan societies. These societies are

governed by the same degree of discipline that prevails in the fire departments of all great cities. The society of Berlin has its various stations in different parts of the city, all connected by telegraph with each other and with the offices of selected medical officers, some of whom are constantly within reach of emergency calls, very much as the ambulance surgeons of our American cities are. These various stations are at all times available to those who are suffering from recent slight injuries, such as do not require the calling of an ambulance. Three or four uniformed men are the usual complement to a station, but whenever a number of additional helpers is needed, there are always men ready, by previous agreement, to respond from the outside. The superintendent of the station may be a paid employee, but the others are ordinarily volunteers, who for the love of the work find their recompense in learning how to relieve their injured fellow-citizens. The hours of duty are so apportioned into day and night watches that one relay of Samaritans relieves another with promptness and without hardship to any. The men are drilled in classes, and by twos and threes, how to carry the injured in their arms or by means of the stretcher, and how to restore suspended animation, stanch hæmorrhage, etc. Not every candidate for the position of volunteer can be accepted, and those especially who at the outset are clumsy and apt to handle a person without tact are not desirable subjects for the drill. There are other and better materials always ready to volunteer—men who are teachable, considerate of others, and light-handed when they come to the relief of the injured. The code of rules that governs the operations of the societies that now exist on the Continent is that of which Dr. von Esmarch is the author.

GUNSHOT WOUND OF THE LIVER.

An interesting case of recovery from a gunshot wound of the liver is reported by Dr. Closs, of the Dunedin Hospital, in the *New Zealand Medical Journal* for April. The number of recoveries after this injury is small. Longmore saw only one case of recovery during the Crimean campaign. Surgeon Otis recorded four recoveries out of thirty-two cases. The Surgeon General's *Circular No. 3* refers to four recoveries out of fifteen cases of this injury. Dr. Closs's patient was a man, aged forty-two years, who attempted to commit suicide with a pistol. This occurred last January. The man was admitted into the hospital with collapse, from both shock and hæmorrhage, with much nervous excitement. The course of the bullet was from the eighth intercostal space in front backward and downward. The bullet, of the conical variety, was extracted on the same day, by an incision made close to the right side of the spine, on a level with the transverse process of the first lumbar vertebra. A drainage-tube was readily passed through the posterior incision about four inches, in a direct line with the wound of inlet. There was no escape of bile, and this fact is quite in accord with the records respecting many similar gunshot wounds. The external wound was kept aseptic, and a dry dressing was used. A slight amount of necrosis of the soft parts about the wound of impact took place. Jaundice and peritonitis were present during convalescence. The man was discharged from the hospital in twenty-four days after the wounding. The highest temperature was observed on the second day—102° F.; the normal temperature was reached about the fourteenth day, and there were only trifling fluctuations after that date. The pulse and respiration were more variable. The ball had undoubtedly passed directly through the liver. When last seen, the patient was able to go about as well as he had done before the shooting.

THE QUESTION OF CÆSAREAN SECTION.

In an article published in the *Centralblatt für Gynäkologie*, Velits agrees with those authors who think that cases of Cæsa-rean section with the relative indication should be reserved for operation in well-appointed hospitals. Two cases of his own are narrated in which both mothers and children were saved. During the suturing of the uterus the cervix was compressed manually. Two rows of sutures were passed. The deep layer included the uterine muscle, avoiding the decidua on the one hand and the peritonæum on the other. As soon as the sutures were passed the compression of the cervix was discontinued, and then a series of peritoneal Lembert sutures was passed. In the first case the uterus remained freely movable; in the second it became adherent by a broad surface to the abdominal wall. In comparing the different methods of operation, that in which compression of the uterus is accomplished by means of an elastic ligature is disapproved of because of the uterine atony which may follow its use. If atony occurs, the author recommends the use of the uterine tampon rather than the Porro operation. For suture material silk is preferred. Although the reported results of repeated Cæsa-rean operations upon the same woman have been favorable, it must be remembered that such operations may be extremely difficult, especially when intestinal adhesions have formed. The author records himself as believing that it is a duty one owes to humanity to sterilize by ligation of the Fallopian tubes those women who have required the operation of Cæsa-rean section and can not be delivered by the natural passages. He also believes that in osteomalacia it is not the Porro operation that is demanded, but the conservative Cæsa-rean section, together with the removal of the tubes.

LUNACY IN IRELAND.

From the *Forty-second Report of the Inspectors of Lunatic Asylums in Ireland* it appears that the total number of the insane under care in the various asylums and workhouses on the 1st of January last amounted to 17,124, being an increase of 436. The previous year also showed an increase of 437. The number of the insane, it may be mentioned, has increased from 249 in 100,000 of the population in 1880 to 369 in 100,000 in 1892; and if to this is added the number of the insane wandering at large, according to the census return of 1891, the proportion would be found to amount to 476 in 100,000. This marked increase, which is absolute, not relative, taken in connection with a diminished population, is of serious import and is altogether unexplained. It calls for special investigation, and steps should be taken to elucidate the problem. As a consequence of the increase, the accommodation in district asylums in Ireland still continues quite inadequate to supply the wants of the insane population. The overcrowding is rapidly increasing, and the necessity for further accommodation is becoming more and more urgent. However, it is satisfactory to learn that the governors of almost every district asylum in Ireland are now fully aware of the necessity of meeting the requirements of their respective districts, and, in a large number of instances, have already sanctioned the necessary expenditure for alterations and additions, so that it is hoped that within a reasonable time the accommodation will be rendered in some degree better adapted to meet the immediate wants of the insane poor.

THE FIRST NAPOLEON AND THE OBSTETRICIAN.

The *Union médicale* quotes from the *Bulletin médical des Vosges* a curious extract from a book by Maze-Sencier entitled

Les Fournisseurs de Napoléon I^r by which it appears that Dr. Dubois attended the empress Marie Louise in confinement. Parturition was protracted and laborious, and Dubois, in his anxiety, acquainted the emperor with his apprehensions. Napoleon said to him: "Act as you would if you were dealing with a *bourgeoise* of the rue Saint-Denis; above all, Dubois, save the mother." Mother and child both were saved, and the emperor caused Corvisart to express his delight to Dubois and to ask what he wished as his reward. Dubois replied that he wanted many honors and a good deal of money. He was made a baron and given 100,000 francs.

BACTERIOLOGICAL INVESTIGATIONS IN THE NORMAL AND THE FEBRILE PUERPERIUM.

VON FRANKE's investigations, published in the *Zeitschrift für Geburtshilfe und Gynäkologie*, have not been extensive enough to warrant comprehensive conclusions, but he feels justified in offering the following: 1. The *Streptococcus pyogenes* which is found in the uterus in recently delivered women, which is usually free from bacteria, causes in only a few cases a slight elevation of temperature, with trifling disturbance of the general condition. 2. The *Bacterium coli commune* may be a cause of puerperal fever. 3. Sapremic fever during childbed is a rarity. It can be absolutely diagnosed only in cases in which a careful bacteriological examination of the lochia shows the absence of the pathogenic micro-organisms and the presence of the saprophytic.

ARTESIAN-WELL WATER AN ALLEGED CAUSE OF FEVER.

FOUR fatal cases of typhoid fever have been reported at Paterson, New Jersey, as due to the above-named cause. Forty cases of the fever are said to have occurred in about a month in a limited district of that city where the supply is drawn largely from two artesian wells. In a single block of that district fourteen cases have arisen. The inculcated water has been examined by the State Chemist, Dr. Wallace, and found to be heavily charged with impurities.

SOMETHING NEW ABOUT SCIATICA.

A NEWSPAPER with a weakness for medical items published the following remarkable statement in a recent cable dispatch regarding the illness of Prince Bismarck: "The sciatica has now reached his arms and prevents him from using his hands, so that it is necessary for his attendants to feed him."

TYPHOID FEVER AND THE ALGERIANS.

ACCORDING to Professor Sezary (*Union médicale*), the aborigines of Algeria enjoy almost absolute immunity against typhoid fever, but typhus is very common among them.

ITEMS, ETC.

The Medical Society of the State of New York.—The following business committee has been announced by the president: Dr. Henry Flood, of Elmira, Dr. L. Bolton Bangs, of New York, and Dr. Edward Clark, of Buffalo, to whom communications regarding papers for the next meeting of the society may be addressed. The next meeting will be held February 6, 7, and 8, 1894.

The Practitioners' Club is the title of a new medical society in Madison County, Kentucky. The officers are: Dr. M. C. Heath, president; and Dr. Clarence H. Vaught, secretary. The meetings are to be held on the second Tuesday evening of each month.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 19, 1893:

DISEASES.	Week ending Sept. 12.		Week ending Sept. 19.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	0	0
Typhoid fever.....	37	11	33	7
Scarlet fever.....	31	1	44	4
Cerebro-spinal meningitis....	6	5	1	0
Measles.....	57	7	41	5
Diphtheria.....	95	28	99	31
Small-pox.....	8	2	18	3

The Richmond Academy of Medicine and Surgery.—At the next regular meeting, on Tuesday, the 26th inst., the subject for discussion will be *Oster's Practice of Medicine* (D. Appleton & Co.), the discussion to be opened by Dr. C. R. Cullen.

The Society of the Alumni of Charity Hospital will hold a meeting on Wednesday, October 4th.

The Death of Dr. Daniel J. MacGowan, of Wenchow, China, at the age of seventy-eight years, removes the oldest American resident in that country. He was a native of Massachusetts, the son of North of Ireland immigrants. Fifty years ago he went out as a pioneer medical missionary of the Baptist, Southern, societies. In later years he accepted a position as medical officer to the British customs service at Wenchow. He also journeyed considerably for the two years last past in Japan, Siberia, and Manchuria, a task apparently too great for his declining years. He was an alumnus, of the class of 1840, of the College of Physicians and Surgeons.

The Death of Dr. William T. White, at the age of sixty-four, took place on Sunday, the 17th inst. He was a graduate of the New York Medical College, of the class of 1858. For several years he was in the medical service of the Panama Railroad. At the time of his death, and for many years before, he was the editor of the *Medical Register of New York, New Jersey, and Connecticut*.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 10 to September 16, 1893:*

MCCULLOCH, CHAMPE C., JR., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Sam Houston, Texas, and ordered to Fort Ringgold, Texas, for duty, relieving PILCHER, JAMES E., Captain and Assistant Surgeon. Captain Pilcher, upon being relieved, is ordered to Fort Niagara, New York, for duty, relieving ROBERTSON, REUBEN L., Captain and Assistant Surgeon. Captain Robertson, upon being relieved, is ordered to Fort Omaha, Nebraska, for duty. LA GARDE, LOUIS A., Captain and Assistant Surgeon, will, upon the completion of his duties in connection with the World's Columbian Exposition, report in person to the commanding general, Department of the Colorado, Denver, Col., for duty as attending surgeon and examiner of recruits in that city.

MIDDLETON, J. V. D., Lieutenant Colonel and Deputy Surgeon General, Leave of absence for one month, to take effect on or about October 1, 1893, is hereby granted, with permission to apply for an extension of fifteen days.

STILES, HENRY R., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Omaha, Nebraska, and will report in person to the commanding officer, Fort Meade, South Dakota, for duty at that post.

WOODRUFF, CHARLES E., Captain and Assistant Surgeon. By direction of the Secretary of War, the leave of absence granted is extended four months.

POWELL, JUNIUS L., Captain and Assistant Surgeon. The leave of absence granted is extended ten days.

HOFF, J. VAN R., Major and Surgeon. Leave of absence for one month is hereby granted.

BAILY, J. C., Colonel and Assistant Surgeon General. Leave of absence for one month is granted, to take effect about the 5th inst.

HEIZMANN, CHARLES L., Major and Surgeon, Fort Douglas, Utah. Leave of absence for one month is granted, to take effect between the 25th inst. and the 5th proximo.

Society Meetings for the Coming Week:

MONDAY, September 25th: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, September 26th: New York Dermatological Society; Buffalo Obstetrical Society; Medical Society of the County of Lewis (quarterly), N. Y.; Practitioners' Club, Madison County, Ky.

WEDNESDAY, September 27th: New York Pathological Society; Metropolitan Medical Society (private); Medical Society of the County of Albany; Auburn, N. Y., City Medical Association; Berkshire, Mass., District Medical Society (Pittsfield); Philadelphia County Medical Society.

THURSDAY, September 28th: New York Orthopaedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private); New London, Conn., County Medical Society (extra, New London); Pathological Society of Philadelphia.

Letters to the Editor.

POISONING BY ARSENIC.

DUBLIN, September 1, 1893.

To the Editor of the New York Medical Journal:

SIR: I am not a medical practitioner, but a barrister; but, feeling some interest in poisoning cases that come before our courts, I wish to ask your able correspondents a few questions on the subject. They arise out of the well-known Maybrick case, which has excited considerable attention on your side of the Atlantic as well as here. The victim is, I believe, being slowly done to death in prison.

1. What is the probable amount of a fatal dose of arsenic in the case of a man of fifty who had often taken arsenic medicinally in considerable quantities?

2. Dr. Stevenson found 0.073 grain of white arsenic in 12 ounces of the liver, the weight of which was estimated at 48 ounces. He found 0.015 grain in 8 ounces of the intestines. In some other parts of the body he found traces too small to be weighed. Was he justified in concluding from these data that the body at the time of death contained "probably" or "nearly" (the latter word is Dr. Carter's) a fatal dose of arsenic? How much arsenic, in the opinion of your able correspondents, did it contain at the time of death? (Mr. Davies found less than Dr. Stevenson.)

3. Is there any ground for the allegation of the judge and of the leading counsel for the prosecution that the arsenic which kills is not that which remains in the system, but that which is eliminated from it? And, if so, is there any difference in this respect between elimination by vomiting and otherwise? (In Mr. Maybrick's case there was a good deal of vomiting and very little diarrhoea. The judge made no distinction between the different modes of elimination. I can find nothing in the medical evidence to justify his statement to the jury.)

4. If a person has taken a fatal dose of arsenic, would his symptoms be alleviated by administering a small quantity of arsenic, as Dr. Humphreys swore they were in the case of Mr. Maybrick?

5. Dr. Humphreys ascribed the long-continued vomiting to a morphia suppository which he administered to the patient. Is morphia known to have had this effect in other cases?

A TRANSATLANTIC BARRISTER.

Proceedings of Societies.

FIRST PAN-AMERICAN MEDICAL CONGRESS.

Held in Washington on Tuesday, Wednesday, Thursday, and Friday, September 5, 6, 7, and 8, 1893.

(Continued from page 333.)

SECTION IN GENERAL MEDICINE.

The President, Dr. VICTOR C. VAUGHAN, of Ann Arbor, Mich., in the Chair.

The Principles of Immunity and Cure in the Infectious Diseases.—The PRESIDENT opened the section by reading a paper with this title. After reviewing the history of the work done, and the advances made by recent experimenters, the speaker detailed his method of procuring and preparing immunizing materials. These fluids, which were exhibited to the section, had been obtained from various organs of the body, and possessed varying degrees of germicidal properties. There seemed to be no doubt that the nuclein-forming organs of the body were mostly concerned in the production of immunity. The nuclein formed by these cells, or in the organs, passed into the blood partly in solution and partly in the form of multinuclear white corpuscles, the so-called phagocytes. The speaker did not want to commit himself to the theory that the entire cell broke down. He referred simply to the fact, and he believed it to be a fact, since he had found nuclein in solution in blood serum, that the nuclein passed from the cell into solution. Whether this process was due to the breaking down of the cell or to an active secretion on the part of the cell he was unable to say. The action of the soluble or alkaline nuclein on germs might be either inhibitory or directly toxic, or both. It was not necessary that the invading germ be killed in order to prevent its producing disease. There must be three factors in the production of immunity in an animal naturally susceptible. First, there must be an inhibiting or immunizing substance introduced into the body. Secondly, the organs whose activity was stimulated by those immunizing agents were those which elaborated nuclein, such as the spleen, the thyroid gland, and bone marrow. Thirdly, the antidotal substances were a form of nuclein. The kind and amount of nuclein found would depend upon the nature of the inciting agent and the condition of the organ or organs acted upon. The word nuclein was used in the broad sense, including the nucleins, nuclein acids, and nuclealbumins. An organ which had been once stimulated by a given excitant responded more quickly the second time to the same excitant, provided the interval of time was not too great. This explained the gradual loss of immunity. Now that we had learned that the animal body itself generated a germicide more powerful than corrosive sublimate, and since we knew how to increase this substance in the blood, and could isolate it and inject it into other animals, renewed hope had come to workers in this direction. The advantage of nuclein therapy over blood-serum therapy was in the fact that it might enable employment of the active substance to be made in larger doses. If it was possible to kill the germs or destroy the bacterial poison after the development of an infectious disease by the introduction of a germicide or a toxicide formed by other cells than those of the infected person, then we might expect that cures for these diseases might be found in the near future.

Forms of Malaria and their Characteristic Features.

Dr. F. A. RISQUEZ, of Caracas, Venezuela, read a paper with this title. The speaker confined himself to the description of malarial diseases as found in his country. He classified them as

follows: Of the intermittent forms, they were generally quotidian, occasionally tertian, and very rarely quartan. The continued forms included the varieties of bilious and icterohæmaturic. Of the pernicious forms, there were the pernicious proper and the complicated. The periodic and continued varieties belonged to the larvate forms. While the paper was largely historical, there were some very good points made in the matter of diagnosis. The forms of the first group were easily recognized by the feature of the paroxysm and by the periodic element. When the attack was prolonged the diagnosis might be difficult. The forms of the second group were distinguished by the gastro-hepatic symptoms and the indications of the urine. They might be confounded with other diseases, especially yellow fever. The third variety was recognized by the pre-existence of malarial paroxysms. It might become almost impossible, however, to distinguish between cholera, pneumonia, or tetanus and cases of choleric form, dysenteric, and pernicious fevers. The forms of the fourth group presented still greater difficulties, especially in the continued varieties. They might assume all the appearances of typhoid fever, of cholera, of dysentery, of paralysis, or of hæmorrhage. The malarial cachexia might simulate tuberculosis, hepatic abscess, etc. In all these conditions an early diagnosis was indispensable, because they required the fearless administration of quinine, and this drug might be contraindicated in the non-paludal diseases. There was but one unquestionable means of diagnosis, and that was the microscopic examination of the blood. As all malarial manifestations were accompanied by melanæmia, and melanæmia presented itself exclusively in malarial disease, the sign was therefore pathognomonic, and every suspected case should be examined. A drop of malarial blood under the microscope showed the masses of black pigment in the plasma. The manipulation required no special technique; any one with average ability could make the test. The blood was usually taken from the end of the finger, and required no staining; it was simply placed on a slide and examined with a power of from two to four hundred diameters. The number and size of the pigment masses were proportional to the degree of malarial poisoning. Whenever they were found the indications were for the administration of quinine. Pigment had been found in all forms of malarial disease; where it had been seen in other diseases it was only an evidence of malarial complication.

Dr. DAVID CERNA, of Galveston, Texas, was very sorry that so large a majority of the listeners had not been able to appreciate the importance and completeness of Dr. Risquez's paper, for he had read it in Spanish. Dr. Cerna was pleased to find so easy a method of accurately deciding whether a given case was malarial or not, as there were many conditions which masked the disease. Of course, if the Laveran micro-organism was found in the blood the diagnosis was undoubted, but it was not every practitioner that was prepared or able to do expert microscopic work. He believed, with Dr. Risquez, that the symptom of melanæmia was pathognomonic of malarial intoxication. This had been confirmed in numerous examinations of the blood, both in cases where the symptoms were not typical and in cases of obscure origin but of undoubted malarial poisoning. In regard to the use of quinine in malarial diseases, the speaker was not sure that it was always the proper drug to use. Because it had sometimes failed to benefit patients supposed to be suffering from malarial disease was, however, no sign that there had been a mistake in diagnosis. Even in cases where the hæmatozoa were found quinine had been known to do harm. As a general thing, if the case was not too chronic and the poisoning too great, and provided the pigment was found, quinine was the proper drug to administer. It had been observed that qui-

nine did not destroy the concentric bodies (hæmatozoa), in fact had no effect upon them. Under these circumstances were we to believe that these micro-organisms were really the cause of malarial disease? The speaker had had excellent results with a new drug, phenocol, in the treatment of obstinate cases of malarial poisoning in which every other remedy had failed.

Dr. T. B. GREENLY, of Kentucky, thought that the word "malaria" as a general term was a misnomer, as there were so many factors at work to produce the class of cases that went under that name, and also that strictly antimalarial remedies in their treatment were valueless. He had seen cases of undoubted malarial poisoning that could not be treated with quinine, but by the combination of chloride of ammonium he was able to avoid the congestion produced by the drug alone. In Kentucky there was a type of fever to which the term typho-malarial was applied. It was most prevalent during the time of the year when malarial fevers were common. It occurred at no other time, and was distinguishable by the character of the pulse, which had no ratio to the temperature. Where the temperature was found to be high the pulse was slow, and sometimes slower than normal, while in remittent fever the pulse was very rapid.

Dr. H. A. WEST, of Galveston, Texas, thought that the point of greatest interest was that of diagnosis between the various fevers. He regarded the presence of the pigment in the blood as important, in that it stamped at once the class of case one had to deal with, and no time was lost in the matter of treatment. He considered that pigment as a means of diagnosis was much more important than the hæmatozoa, because it was so much easier of discovery. As to the cause of the pigment in the blood, it was thought to be due to the destruction of the corpuscles and not due to the malarial poison. The speaker thought that these masses of pigment could exist in typhoid fever and yellow fever. He had made it a practice to examine the blood in every case of fever that came under his care, and he had found pigmentary masses coincidently with other diseases. It was not to be understood that he had found these conditions to exist in the blood unless malarial disease really was present. In regard to Dr. Cerna's statement that in some cases of malaria quinine was valueless as a remedy, the speaker thought that an explanation could be found in the fact that in some cases of malarial poisoning the disorganization had been so great that the quinine had nothing left to act upon.

Dr. Risquez wanted to emphasize the principal points brought out by his paper: 1. That the presence of pigment in the blood pointed conclusively to malaria. 2. That he had examined cases of yellow fever and typhus fever during epidemics, and had been unable to find even a trace of pigment. 3. That in some isolated cases of yellow fever he had found pigment which seemed to point to a hybrid disease. If, after finding the real pigmentary masses, further proof was needed of their genuineness, the addition of dilute sulphuric acid would settle the question. The author used the mineral acids as reagents in his examinations, and said that if the pigment was not dissolved they were malarial.

(To be continued.)

SECTION IN DISEASES OF THE MIND AND NERVOUS SYSTEM.

The President, Dr. C. H. HUGHES, of St. Louis, in the Chair.

The President's Address.—Before proceeding to the scientific work the president called attention to the modern advances of neurology, and referred especially to the contributions of neurologists to general medicine. He spoke at length regarding the brilliant achievements of American physicians in this special field, and gave a brief historical outline of the work accomplished during the present century. He said that America

bred and developed neurologists as the water bred and developed fishes. The tabulum neurology fed on was in the American people—their hustling, rushing habits, their business, professional, social, and political environment, and the numerous newspapers they read every morning before breakfast and every night before they forgot to say their prayers—this moral, political, social, and business atmosphere of ambition and bustle tended to develop the strongly endowed, neurologically and psychologically, as it tended in the weakly endowed to the development of neuropathic conditions. It developed neurologists and psychologists to care for the neuropaths. It built and it broke the nervous system. It could not yet be said that we were a neuropathic people, though we were tending that way; but neurology was advancing with equal pace with neuropathic break-down, and would, it was hoped, ultimately enlighten and save the people from their neuropathic sins.

An Address in Spanish was then delivered by Dr. WILLIAM A. HAMMOND, of Washington, and it was responded to by Dr. Manuel Carmona y Valle, of the City of Mexico.

Cerebral Spastic Paralysis in the Adult.—Dr. CARMONA, of Mexico, read a paper with this title.

The Prognosis of Railway Spine.—Dr. F. X. DERCUM, of Philadelphia, read a paper with this title. He described briefly a case in which a blow on the back had been followed by the usual symptoms of painful back associated with neurasthenia and hysterical symptoms. The case was considered as a typical one of "railway spine," so called, without the element of litigation. It was therefore considered as a suitable case in which to test the possibilities of the rest-cure, which might perhaps enable one to answer the question so often asked of the medical witness in court: "Will the patient recover, and if so, how long a time will it require?" After five months and a half of treatment in a special hospital an almost complete recovery had ensued.

Dr. BROWER, of Chicago, expressed the view that the paper possessed many valuable suggestions as to diagnosis. The cases seen by him in Chicago had seemed to be of a different character, and had not presented so many objective symptoms. The manifestations in Dr. Dercum's case had undoubtedly been the result of either neuritis or meningitis.

Dr. FULLER, of Grand Rapids, had treated a case with similar symptoms by puncturing the spinal membranes and removing some of the accumulated fluid. The operation had been successfully repeated several times.

Dr. DERCUM said he thought the muscles and ligaments suffered most, and that the psychical symptoms indicated neurasthenia.

The Treatment of Cerebral Hæmorrhage.—Dr. D. R. BROWER, of Chicago, read a paper with this title. He spoke of the various methods of treatment with the view of controlling arterial tension and diminishing arterial degeneration. He also referred to the beneficial administration of strychnine and the favorable result from the application of the galvanic current to the brain for the relief of the hemiplegia.

Dr. H. A. HARE, of Philadelphia, did not believe that the galvanic current acted directly upon the brain structure, but might hasten absorption in a reflex manner. He was of the opinion that the current, as applied to the head with moistened electrodes, did not pass through the brain at all, but merely sought the path of least resistance, and therefore only traversed the scalp.

Dr. CARMONA, of Mexico, considered electricity of no value when secondary degeneration had occurred.

Dr. ROQUE MACONZET, of Mexico, was of the same opinion.

Dr. W. M. LESZYNSKY, of New York, said that the subject was of the greatest importance to the general practitioner, and it

required a comprehensive knowledge of general medicine to manage this class of patients. He thought that such a complication as ankylosis of the shoulder joint was generally avoidable in hemiplegics if passive motion was begun early and persisted in. Strychnine was of value only as a tonic, and did not improve the paralysis. He had never noticed any beneficial effect that could be attributed to the use of galvanism applied to the head.

Dr. DERCUM was opposed to the use of strychnine on account of the probability of hastening contracture. He agreed with Dr. Hare in reference to the use of electricity.

The President thought that galvanism did not always produce its direct action on the brain, but it was not impossible for the current to pass directly through the brain in the living body.

Dr. A. D. ROCKWELL, of New York, believed that the symptoms produced seemed to indicate that the current acted directly on the brain.

Organic and Mental Co-ordination.—Dr. WILLIAM FULLER, of Grand Rapids, read a paper with this title. His intention was to point out the relations existing between the nutritive conditions of the organs of the body and the mental feelings related to the individual organs, which were co-ordinated not only in their nutrition from the blood, but also by nervous connections so as to produce a frame of mind which corresponded to the general nutritive condition of the organs of the body as a whole. The practical conclusion was that the mind might be influenced by alterations of the physical processes and that the nutrition of the body was influenced by the mental states of emotion and belief. Illustrations were given in support of the theory advanced. In the author's opinion the cerebellum was the brain of the organic nervous system, and though it was not the seat of the emotions, which were conscious feelings and properly belonged to the cerebrum, yet those feelings were produced by cerebellar states.

Dr. BROWER said that it was to be regretted that Dr. Fuller had not given reasons for assigning functions to the cerebellum which had been attributed to it and discarded many years ago.

Should Inebriates be punished by Death for Crimes committed while Intoxicated?—This paper was read by Dr. T. D. CROTHERS, of Hartford, with the following conclusions:

1. The legal treatment of insanity has changed in obedience to a more accurate knowledge of the brain and its diseases.
2. The legal treatment of inebriety is unchanged to-day. Although it occupies two thirds of the time of the courts, all teachings of science and a larger knowledge of the inebriate and his malady are ignored.
3. The ruinous error of punishment by fines and imprisonment of inebriety and petty crimes associated with it, which notoriously increases and perpetuates inebriates and criminals, is a fact demonstrable in every community.
4. Thus public opinion, through mediæval theories and laws, is training and preparing a class of inebriates who first commit petty, then capital crime, with a certainty that can almost be predicted.
5. The death penalty for such crime utterly fails for the same reason. The execution of any number of this class simply opens the door for an army already prepared and trained to take their places.
6. From a scientific study of these persons, it is clearly apparent that they are diseased and incapacitated to act sanely. Alcohol has palsied the brain and made them madmen. The very fact of continuous use of alcohol is evidence of mental impairment and unreasoning act and thought.
7. To hold such men accountable for their acts and by pun-

ishment expect to deter them from further crime, and by such punishment check others from similar crime, is an error which both scientific teaching and experience point out.

8. The object of the State, through the law, is to protect society and the individual; but if the execution of the law-breaker fails to accomplish this end, the laws are wrong.

9. The unfounded fear that the plea of insanity in crime, and the failure to punish, encourage further crime, is flatly contradicted by statistics.

10. Among the mentally defective, the insane, and inebriates, the death penalty is followed by an increase rather than a diminution of crime.

11. The inebriate should never be hung for crime committed while under the influence of alcohol.

12. This method of punishment is never deterrent, but furnishes an attraction for other inebriates, who commit similar crime in the same way, following some law of mental contagion.

13. The inebriate murderer should be confined for the rest of his life in a military workhouse hospital. He should be under the care of others, as incapacitated to enjoy liberty and incompetent to direct his thoughts or acts.

14. A change of public sentiment and law is demanded, and a readjustment of theory and practice called for. The criminal inebriate occupies a very large space among the armies of the defective who threaten society to-day, and his care and treatment must be based on accurate knowledge, not theory.

15. Inebriate murderers should never be placed on public trial, where the details of the crime are made prominent or the farcical questions of sanity are publicly tested. They should be made the subject of private inquiry, and placed quietly in a workhouse hospital, buried away from all knowledge or observation of the world.

16. The contagion of the crime and punishment would be avoided, and the inebriate's services might repair some of the losses to society and the world.

A New Process for Extracting the Essential Principles of Certain Animal Organs, and on their Physiologic and Therapeutic Properties.—This was the title of a paper read by Dr. W. A. HAMMOND, of Washington. It was possible, by the process described, he said, to obtain from the tissues of the various organs of the body—such as the brain, the heart, the spinal cord, the testes, the ovaries, the muscles, and the thyroid gland—substances which were possessed of powerful physiological and therapeutical properties. There was much evidence to show that the active principle of each of these animal extracts acted by preference on that organ of the body which was analogous to that from which it had been derived. Thus "cerebrine" particularly affected the brain; "medulline," the spinal cord; "cardine," the heart; "testine," the sexual system of men; "ovarine," the sexual system of women; "musculine," the muscles; "thyreoidine," the thyroid gland, etc.—and this not only physiologically, but to some extent, at least, in suitable cases, therapeutically. It had not yet been determined whether the active principle (or principles, for there might be more than one agent in each) existed primarily in the organs acted upon by the menstruum, or was a secondary product of the nature of leucemine. They all acted, in the first place, as disturbers of the vaso-motor system, some of them producing a paralyzing and others a spastic effect. And it was not the case that this effect was the same in all instances with the same extract. Thus "cerebrine," although generally causing a sensation of fullness in the head, slight headache, flushing of the face, suffusion of the eyes, etc., sometimes produced paleness, slight vertigo, and a sensation of faintness. This variability was apparently due to the size of

the dose, the state of the system at the time of administration, or the nature of the disease for which the extract was given. In these respects there was an analogy with the action of other substances used as medicines and with that of certain remedial agents other than drugs. Among the first named were opium and its active principles, quinine, cocaine, alcohol, etc.; among the latter, electricity, heat and cold, massage, exercise, etc. In the use of these extracts, as well as in the employment of every therapeutical agent, it was necessary for the physician to familiarize himself as thoroughly as possible with the constitution, habits, and inherent proclivities of his patients. No ill effects, general or local, had ever, in the author's experience, followed on the administration of any of these animal extracts, whether they had been given hypodermically or by the mouth. The dose was so small that when taken upon the tongue it could not be swallowed, but was absorbed rapidly from the mucous membrane of the mouth. Finally, while it was too soon to draw definite conclusions relative to the effects of these extracts in curing organic diseases, there was abundant evidence to show that they exerted a beneficial influence in such affections and that they were rapidly curative of many so-called functional disturbances. This was especially the case in regard to "cardine" in certain cardiac disturbances, "cerebrine" in nervous weakness (neurasthenia), and "testine" and "ovarine" in aberrations of the sexual system in men and women respectively.

The PRESIDENT looked forward to great possibilities from the employment of animal extracts. He thought we were in danger of falling into the same attitude of skepticism in this matter as had been shown toward Jenner, Morse, and Cyrus Field.

The Symptoms and Treatment of Partial Epilepsy was the title of a paper read by Dr. ROQUE MACONZET, of the City of Mexico. His method of treatment was governed entirely by the cause of the disease. He believed that antisypilitic medication was often useless and that surgical interference was frequently necessary.

Dr. A. B. RICHARDSON, of Columbus, Ohio, expressed the opinion that the treatment advised by Dr. Maconzet was the only rational and accepted method.

Dr. BROWER, of Chicago, considered an operation alone insufficient to establish a cure; it merely served as an adjunct to constitutional treatment.

Dr. DEECUM, of Philadelphia, said these operations had been performed frequently in his city with much benefit, but without absolute cure. In the main he agreed with the previous speaker.

Erotopathy; Morbid Erotism.—The PRESIDENT read a paper with this title, and formulated the following conclusions:

1. Morbid erotism presents both normal and abnormal psychological aspects. It therefore presents a voluntary deviation from the ordinary and natural indulgence of the genesis instinct—the normal but immoral psychology of the eroto-sexual propensity, and instinctive, inherent, organic, dominant, and often resistless involuntary perversions of this passion, the latter being the true abnormal and organically unnatural sexual perversion, the reverse or contrary sexual instinct. This is the psychiatric aspect of the subject, the one that most concerns us as alienists and neurologists.

2. Love and the genesis sense are not one, as is shown in the antedating of love by the appearance of the sexual feeling, in the developmental period up to puberty, and its survival beyond the menstrual climacteric in women. In the organic evolution of the individual love antedates the birth and survives the decay of the sexual feeling, though it is intensified, or diminished, or otherwise modified or influenced by sexual states.

3. The duty of the hour is to search out the complicating neurological and neuropathic factors and the predetermining neuropathic conditions, the neurology, immediate and ancestral, of these unique morbid and unnatural eroto-genetic perversions; to weigh in conjunction the potentialities of physical or psychical environment, and determine as satisfactorily as we may, in the light of clinical and historic facts and physiological and pathological states, the true mental status of the eroto-sexual pervers.

4. This inquiry involves a study of hystero-erotic attachments and aversions, erotic trances, ecstasies, beatitudes, divine amours, immaculate conceptions, etc., as well as the true *contrare Sexualempfindung*, or psychopathia sexualis. It involves also certain morbid erotic perversions sometimes observed in epileptically insane women, such as vaginal mutilation with glass, pins, and needles *inter vaginam*, etc., epileptic and neurasthenic exhibitions, etc. We include all under erotopathia.

In every study of morbid erotism, he said, the distinction between love and lust should be sharply drawn, as between healthy erotism and perverted or debased sexual passion. This was necessary to a proper understanding of those historical and every-day recorded instances of pure but perverted Platonic affection and those oft-recurring and startling reversions of sexual love into murderous hate and passion, so often chronicled in the public press. While Science should cast the mantle of charity over morbid impulsions yielded to in resistless psychopathic states, it must draw the line between similar impulsions (depraved and but slightly, if at all, morbid) cultivated and gratified in normal psychical conditions. It must separate disease from depravity of mind, and herein lay the difficulty of his subject. The question of crime and insanity, often difficult to solve, devolved upon us as medico-jurists to determine from known and yet to be acquired psychologic and psychiatric data. The subject was primarily neither one of sentiment nor one of morals exclusively, but mainly one of psychiatry, to the study of which the data of alienism and psychology should be rigidly applied in all questions of medical, moral, and forensic inquiry.

Dr. CROTHERS, of Hartford, said that with such an array of symptoms, in his opinion, it was impossible to consider such persons other than insane.

Dr. J. K. KING, of Watkins, N. Y., thought there was great difficulty in determining where moral depravity ended and insanity began. He cited illustrative cases and concluded that all the subjects could not be classified as insane.

Dr. MACONZET, of Mexico, expressed the view that erotopathia might be produced by either peripheral or centric causes. He had seen several cases in women. Some had been occasioned by disorders of the genital apparatus, while in others no physical abnormality had been found.

The Treatment of Nervous Diseases in Sanitariums.—This was the title of a paper by Dr. J. K. KING, of Watkins, N. Y. He said there was great danger at the present day of specialties being too much divorced from each other. He made a plea for their closer union and more harmony in treatment. This was best accomplished, especially in chronic nervous diseases, in medical institutions. The various requisites necessary to make a sanitarium more than a sanitary resort and to make it worthy of the confidence of the medical profession existed in the varied methods of treatment and the advantage of constant supervision. He also discussed the great advantage of occupation, regularity of life, and healthful surroundings in addition to systematic treatment.

Diseases of the Gangliated Nerves was the title of a paper read by Dr. CHARLES K. MILLS, of Philadelphia. He first referred to certain erroneous views as to the gangliated nerves. Even to the present day fanciful views regarding the so-called

sympathetic nervous system were held by the profession at large, which was in part his reason for presenting this paper to the section. The name "sympathetic" had had much to do with perpetuating these errors. He argued that the ganglia of the gangliated nerves constituted lower, local, decentralizing levels of the nervous system. He mentioned the following as the diseases which might be regarded as genuine affections of the gangliated nerves: 1, certain vaso-motor neuroses of the extremities, such as erythromalgia, *digiti mortui* (dead fingers), Raynaud's disease or symmetrical gangrene, angioneurotic oedema, and some forms of acroparesthesia; 2, certain local vaso-motor and trophic affections, such as perforating ulcer of the foot, Morvan's disease in some instances, and various pigmentary and other skin affections; 3, unilateral and localized sweating; 4, some forms of pupillary dilatation; 5, tachycardia and probably other varieties of disorder of heart rhythm; 6, some varieties of changed arterial tension; 7, anasarca from deficient vaso-motor tonus and unassociated with organic disease of the heart or kidneys; 8, some varieties of arthropathy; 9, some varieties of lymphopathy; 10, some forms of isolated and diffused neuritis, such as of the cervical gangliated cord of the great and lesser splanchnics or of the pelvic splanchnics or *nervi erigentes*; 12, some painful sensory disorders not neuritic in character, but which gave rise to mediastinal, pulmonary, abdominal, and pelvic neuralgias; 13, probably various reflex disorders.

The Modern and Humane Treatment of the Morphine Disease.—Dr. J. B. MARTINSON, of Brooklyn, read a paper with this title.

Hypnotism: Does it Menace the Public Weal?—This paper was read by Dr. FRED. C. VALENTINE, of New York. He concluded as follows:

1. The therapeutic possibilities of hypnotism are not denied. A patient who persuades himself, or is persuaded, that he can be cured by the hypnotic influence is as well or better cured than by drugs or appliances that do not appeal to his view of the case.

2. The hypnotic state should never be allowed a status in law or morals. While it is certainly better that a hundred rogues escape than that an innocent being be punished, there is no human mind conceivable that can be induced by hypnotic suggestion to do what its owner knows to be wrong. Those "moral defectives" who can not distinguish right from wrong are proper subjects for the insane asylum.

If these propositions were established, hypnotism would, the author thought, have its status defined and thus would be deprived of all power for evil. It must be clearly understood that no one could be hypnotized without his own full consent and co-operation; consequently any violation of the law of the land or even of an unwritten code of morals while under the alleged "influence" was as punishable as if committed in full, independent possession of the mental faculties. With this view everywhere accepted and established, hypnotism would no longer be a menace to the public weal.

Dr. C. G. COMEY, of Cincinnati, believed that in the hypnotic state there was an abeyance of voluntary power. He thought the condition was allied to the dream-life, and that a man was as irresponsible when in the hypnotic state as he was in his dreams.

Dr. CHARLES K. MILLS, of Philadelphia, said that the reader of the paper had treated the subject in a very illogical manner. He thought it would be unfortunate, both for law and for morals, if hypnotism was made an excuse or defense for crime.

Dr. BROWER agreed with Dr. Mills. In his experience, there were extremely few persons susceptible to the influence of hypnotism. We could no more formulate any law controlling

all cases of alleged hypnotism than we could in regard to all cases of insanity.

Dr. A. B. RICHARDSON, of Columbus, Ohio, regarded hypnotism as of some therapeutic value, but its indiscriminate use was dangerous to society. Public exhibitions of it were a crime against public policy, and its practice should be limited to physicians.

Dr. G. M. HAMMOND, of New York, had found the most susceptible subjects among foreigners. He had discarded the use of hypnotism to a great extent, and had seen only occasional amelioration of symptoms effected by it, but no cure.

Dr. JUAN PADILLA, of Guatemala, thought the writer of the paper had not sufficiently demonstrated the advantages offered by hypnotism, not only as a therapeutic agent, but also as a medium that might in certain judicial cases serve to bring out the truth.

The PRESIDENT said the possibility of hypnotization was a well established fact. It should not be used as a plea in extenuation or defense of crime. It would be important to note the method by which hypnotism was accomplished. He designated it by the term "somnambulism" and defined it as a condition of the absence or subjection or abeyance of the volition due to the induced sleep state.

Dr. VALENTINE said that he had only presented his paper in abstract. He believed, however, that every patient who had been hypnotized had been humbugged. He was of the opinion that ere long hypnotism and works on the subject would be relegated to the galleries of ancient discarded medical curiosities.

The Discrimination between Ordinary Paretic Dementia and Tabes Dorsualis and Syphilitic Cerebral and Spinal Disease simulating the Former.—This was the title of a paper read by Dr. E. C. SPITZKA, of New York. It was discussed by Dr. DEKRUUD and Dr. MILLS, of Philadelphia.

Papers read by Title.—The following papers were read by title: The Curability of Inebriety, by Dr. J. G. Reed, of Elmwood Place, Ohio; The Traumatic Psycho-neurosis: its Relations to Paranoia, Epilepsy, and Paretic Dementia, by Dr. J. G. Kiernan, of Chicago; Suppurative Meningitis and Myelitis, with Exhibition of Specimens, by Dr. Graeme M. Hammond, of New York; Chorea, by Dr. Charles H. Brown, of New York; A Study of the Temperature in Twenty-five Cases of General Paralysis of the Insane, and The Present Status of Infantile Cerebral Palsies, by Dr. Frederick Peterson, of New York; The Successful Management of Inebriety without Secrecy in Therapeutics, by Dr. C. H. Hughes, of St. Louis; The Medical Treatment of Insanity, by Dr. Edward C. Mann, of Brooklyn; Where the New-born Baby learned to Suck, by Dr. C. A. F. Lindorme, of Atlanta; The Influence of Alcohol upon the Human Powers and Constitution, by Dr. T. L. Wright, of Bellefontaine, Ohio; The Disease of Inebriety and its Treatment, by Dr. T. D. Crothers, of Hartford; Neuro-angiolysis and its Relations to Paretic Dementia, by Dr. Frank C. Hoyt, of Clarinda, Iowa; Civil Service in American Hospitals for the Insane, by Dr. S. V. Clevenger, of Chicago; La Renguera, by Dr. Daniel Guterrez y Arango, of Colombia; The Nervous Symptoms of Storms, by Dr. Curran Pope, of Louisville; A Peculiar Type of Vaso-motor Neurasthenia (the Pulsating Disease), with Report of and Operation for the Same, by Dr. Charles L. Dana, of New York; Nutrition against Stimulation, by Dr. W. H. Maxon, of St. Louis; The Study of Criminal Anthropology and Social Reform, by Dr. Abundio Aceves, of Guadalajara, Mexico; Expert and Opinion Evidence, by Clark Bell, Esq., of New York; and On the Judicial Recognition of Irresponsibility in Alcoholic Mental Disease, by Dr. Norman Kerr, of Great Britain.

Book Notices.

Sciatica. A Record of Clinical Observations on the Causes, Nature, and Treatment of Sixty-eight Cases. By A. SYMONS ECCLES, M. B. Aberd., Member Royal College of Surgeons, England, etc. London: Macmillan & Co., 1893. Pp. viii-88.

The author frankly states in his preface that his *opusculum* has no claim to novelty, either in the views that it expresses about the nature of sciatica or in the methods advocated for its relief. There is an exposition of the usually accepted views on the aetiology, pathology, symptoms, and treatment of sciatica, with commentaries on the author's experience with sixty-eight patients affected with this disease.

Reactions. A Selection of Organic Chemical Preparations Important to Pharmacy in regard to their Behavior to Commonly-used Reagents. By F. A. FLÜCKIGER, Ph. D., M. D. Translated, revised, and enlarged by J. B. NAGELVOORT, Analytical Chemist, etc. Authorized English Edition. Detroit: George S. Davis, 1893. Pp. x-154.

Dr. FLÜCKIGER's work describes the methods of obtaining the reactions of the more important organic substances that are used in pharmacy, and this particular edition has the advantage of the addition of the translator's experience.

BOOKS, ETC., RECEIVED.

The Throat and Nose, and their Diseases. With One Hundred and Twenty Illustrations in Color, and Two Hundred and Thirty-five Engravings, designed and executed by the Author, Lennox Browne, F. R. C. S. E., Senior Surgeon to the Central London Throat and Ear Hospital. Fourth Edition. Philadelphia: Lea Brothers & Co., 1893. Pp. xx-734.

A Manual of Medical Treatment or Clinical Therapeutics. By I. Burney Yeo, M. D., F. R. C. P., Professor of Clinical Therapeutics in King's College, London, etc. With Illustrations. Vol. I. Pp. xiii-631. Vol. II. Pp. vi-744. Philadelphia: Lea Brothers & Co., 1893.

The Art of Preserving Health. Outlines of Practical Hygiene adapted to American Conditions. By C. Gilman Currier, M. D., Visiting Physician to the New York City Hospitals, etc. New York: E. B. Treat, 1893. Pp. v-468.

A Manual for Boards of Health and Health Officers. By Lewis Balch, M. D., Ph. D., Secretary State Board of Health of New York. Albany: Banks & Brothers, 1893. Pp. 4-5 to 242.

Therapeutics of Cholera (Cholera Asiatica). By P. C. Majumdar, M. D., Graduate of Medical College, Calcutta, India. Philadelphia: Boericke & Tafel, 1893. Pp. iv-5 to 102.

Die Beziehungen des Sehorgans und seiner Erkrankungen zu den übrigen Krankheiten des Körpers und seiner Organe. Von Dr. Max Knies, Professor e. o. an der Universität Freiburg i. B. Zugleich Ergänzungsbuch für jedes Hand- und Lehrbuch der inneren Medizin und der Augenheilkunde. Mit 21 Figuren im Texte. Wiesbaden: J. F. Bergmann, 1893. Pp. xi-484. [Preis, 9 Marks.]

Transactions of the Medical Society of the State of Pennsylvania at its Forty-third Annual Session, held at Williamsport, 1893. Volume XXIV. Published by the Society.

The Successful Treatment of Typhoid Fever. A Reply to Dr. Page. By Charles Milton Buchanan, M. D., Washington, D. C. [Reprinted from the *Medical Brief*.]

A Study of the Aetiology of Asiatic Cholera, with Suggested Treatment. By M. J. Crouch, M. D., Union, Ky. [Reprinted from the Cincinnati *Lancet-Clinic*.]

Insomnia. By Curran Pope, M.D., Louisville, Ky. [Reprinted from the *American Medico-surgical Bulletin*.]

Suppurative Appendicitis. By L. H. Laidley, M.D., St. Louis, Mo. [Reprinted from the *Journal of the American Medical Association*.]

Experiences in Pelvic Surgery. By A. V. L. Brokaw, M.D., St. Louis, Mo. [Reprinted from the *Transactions of the Southern Surgical and Gynecological Association*.]

Peritonitis from a Surgical Standpoint. By A. V. L. Brokaw, M.D., St. Louis, Mo. [Reprinted from the *Medical Fortnightly*.]

A Synopsis of Clinical Surgery during the Service of Samuel H. Pinkerton, M.D., Surgeon to the Holy Cross Hospital. By Franklin A. Meacham, A.B., M.D., Assistant Surgeon to the Holy Cross Hospital, Salt Lake City, Utah. For the Year 1892.

Suturing the Tendo Achillis in the Correction of Deformities of the Feet. By H. Augustus Wilson, M.D., Philadelphia. [Reprinted from the *International Medical Magazine*.]

A Practical System of Studying the German Language. For Physicians and Medical Students. For Self-instruction. A Modern Simple and Practical Method, enabling Physicians and Medical Students to acquire in a very Short Time and with comparatively but Little Effort, the "Medical" as well as Common "Conversational" German Language. By Albert Pick, M.D. Part II. Newtonville, Mass.: E. S. Tanner.

New Inventions, etc.

AN IRRIGATING TUBE.

By T. J. SHUELL, M.D.,
PARNELL, IOWA.

THE accompanying cut shows the irrigating tube referred to in my article on the treatment of typhoid fever, which appeared

in the issue of the *Journal* of September 2d. It is here shown attached to a fountain syringe, the manner in which I use it. It consists of a tube of medium soft rubber, very smooth, the distal end polished, about three feet in length, and from a half to five eighths of an inch in diameter—25 to 32, American scale (36 to 48, French scale). Tubes of this caliber, I find, will more readily pass the sigmoid flexure than those of a smaller caliber. For children, tubes of 10 to 16, American scale, and about eighteen to

twenty-four inches in length, are suitable.

The tubes of this kind, manufactured by Tiemann & Co., of New York, are admirably adapted, because they are very smooth and have about the right amount of stiffness. I feel

assured that the treatment of all intestinal diseases due to ptomaine poisoning may be made more successful by the irrigation method.

Miscellany.

The Neuroses of the Menopause.—Dr. Gustavus Eliot, of New Haven, whose published writings are all readable and instructive, contributes to the September number of the *American Journal of the Medical Sciences* an article entitled *The Disorders of the Nervous System associated with the Change of Life*. After mentioning women's habitual disregard of their health in their earlier life and the frequency of occurrences calculated to beget emotional disturbances between the fortieth and fiftieth years of age, he says:

"If you inquire carefully in regard to the clinical history of one of these patients, you will find that she suffers from more or less of the following symptoms: Indisposition for exertion, inability to work, forgetfulness, headache, dizziness, insomnia, flushes of heat followed by chilly sensations, sweating, palpitation, flatulence, abdominal distention, and constipation. On making further examination you will probably find that her heart and lungs show no evidence of any organic lesion, and that her flesh is flabby, her pulse soft, her tongue coated, and the conjunctivæ are pale. She may have considerable intercostal neuralgia and frequent backaches, and tender spots may be detected in her head, back, and chest. She also sometimes complains of swelling of the face, hands, and feet, which, however, is often not a real oedema.

"A study of the clinical history of these cases, and a consideration of the inconstant and changeable character of the symptoms, is sufficient to convince one that they are not of organic origin; that they are not associated with any distinct pathological change in the nervous system, but that, on the other hand, they may occur in connection with a variety of different conditions.

"In some cases a disordered digestion is the most important factor in the causation and perpetuation of these very distressing symptoms. The chief disturbance may be in the stomach. The eructations of gas and flatulent distention of the stomach are frequently the most annoying and most important symptoms. Or, on the other hand, the intestines and the associated glands may be chiefly at fault, and the most marked symptoms obstinate constipation and flatulent distention of the abdomen. Not infrequently these two conditions are found coexisting in the same case. They may then give rise to or be associated with a number of other symptoms, the most common of which are headache, dizziness, palpitation, and dyspnoea.

"In some cases anæmia is an important element. This may be associated with disturbances of digestion, either as cause or effect. If both exist, each may intensify and aggravate the other. If anæmia is present, the patient usually complains of headache, dizziness, and dyspnoea.

"In other cases insomnia is a prominent feature. This also may be a result of pre-existing derangements of function of various organs, and in turn, when present, may aggravate other disorders.

"Finally, in many cases there is a distinct and well-marked element of nervous exhaustion. This is frequently the starting point of other disorders, and when they are fairly established is intensified by them.

"In making the diagnosis of this condition one should be very careful to exclude the possibility of the existence of any organic disease. In many cases organic diseases are accompanied by symptoms which resemble those which have been described as of frequent occurrence in connection with those functional disorders of the nervous system which are the subject of this paper.

"Careful exploration must be made of the chest—of the lungs, but more particularly of the heart, to which many patients think that their troubles are referable—in order to detect the possible presence of commencing or latent organic disease. Careful analysis of the urine should be made occasionally, in order that no organic change in the kidneys

may escape notice. The temperature should be taken now and then, especially if the action of the heart is at all accelerated, so that no febrile disturbance may be overlooked. Naturally inquiry should be made as to the manner in which each organ of the body is performing its function, and any deviation from the normal must be carefully noted and duly considered in deciding upon a plan of treatment.

"The prognosis of these disorders is rather uncertain on account of the variety of circumstances which influence their progress. Many patients are exceedingly dilatory in seeking medical advice for these troubles. Many are very negligent about following up the treatment which is prescribed, and some fail to receive proper treatment because their physicians make an erroneous diagnosis, or do not understand what therapeutic measures are adapted to the case.

"The natural tendency of these disorders is to persist for months and years. They do not, however, have any inherent tendency to terminate in death. With proper treatment their severity may be mitigated and their duration very much abbreviated. If the patient seeks advice early, is judiciously managed, and follows up the treatment conscientiously and persistently, the prognosis is good. Care must be exercised to remove, as far as possible, the conditions which permitted the development of the symptoms in the first place, lest they return again after treatment has been discontinued.

"In the management of these cases it is necessary to combine very careful hygienic regimen with appropriate medicinal treatment. Worry and care must be avoided as far as possible. Regular and prolonged rest must be secured. A moderate amount of mental occupation during waking hours is useful. Abundance of fresh air and moderate exercise are essential. Food which can be easily digested and which has been properly prepared must be taken regularly and in sufficient quantity. It must be eaten slowly and chewed thoroughly, and time must be allowed for the process of digestion to become fairly established before the resumption of mental or physical exertion. Tea and coffee must be entirely abandoned, and abundance of milk and water must be taken. Bathing and rubbing influence very favorably the circulation and the processes of nutrition. The body must be properly protected, so as to maintain an equable degree of warmth throughout, care being taken to avoid the extremes of an excess or a deficiency of clothing.

"If the functions of any organ are not properly performed, the treatment must be so directed as to restore and maintain the normal action.

"The digestive organs are perhaps more frequently deranged than any others, and require most careful attention to secure a proper performance of their functions. Constipation, flatulence, and anorexia are the most common and the most important indications for treatment. If constipation exists alone, a pill of aloes and myrrh taken at night, and followed, if necessary, by another in the morning, will generally produce a pleasant effect. Another excellent pill under these circumstances is one containing one fifth grain of aloin and one sixtieth grain of sulphate of strychnine. Two or three of these may be taken at different times through the day, if one at night is not sufficient. The object to be aimed at is to secure one easy movement of the bowels each day, unaccompanied by nausea or griping, by means of small doses, repeated if necessary, of some not very irritating laxative.

"If anorexia, constipation, and flatulence are all present, a bitter mixture will generally prove useful—a combination of nux vomica, cascara sagrada, cardamom, and gentian, with aromatics, is exceedingly valuable under these circumstances.

"If anemia is well marked, iron and arsenic are very useful. If there is no, or only slight, disturbance of the digestion, pills containing sulphate of iron with carbonate of potash, known as Bland's pills, with the addition of arsenous acid, produce excellent results.

"If constipation accompanies anemia, a pill or capsule containing arsenous acid, aloes, nux vomica, and reduced iron may be advantageously prescribed.

"If neuralgia is a prominent symptom, five-drop doses of fluid extract of gelsemium will give relief in many cases. In connection with gelsemium, or in place of it, benefit will often be obtained from the use of sulphate of quinine with extract of hyoscyamus.

"If the nervous symptoms are not accompanied by derangement of

the functions of other organs, or if they persist after proper attention has been paid to the regulation of these disorders, it is necessary to prescribe remedies which act more directly upon the nervous system. The most useful drugs of this class are bromide of sodium, phosphorus and its compounds, nux vomica, and arsenic.

"The use of arsenic has been already mentioned in connection with the management of cases in which anemia is an important factor. In the treatment of certain forms of anemia it is of great value. But besides increasing the production of red blood-cells, it unquestionably possesses the power, also, of promoting the nutrition and vigor of the nervous system. In combination with iron and nux vomica it is exceedingly useful.

"The utility of phosphorus as a nerve tonic has long been recognized. A combination in pill form of one one-hundredth grain of phosphorus with one quarter grain of extract of nux vomica has been used extensively and with excellent effect. One great drawback to its use is the difficulty of securing pills which have been properly made and in which the original characteristics of the drugs have been retained.

"Phosphide of zinc is frequently substituted for phosphorus. One tenth grain of this compound with one fourth grain of extract of nux vomica will often prove of benefit.

"The compound syrup of the hypophosphites is another preparation which is very popular with the profession, and which has positive value as a nerve tonic.

"As a palliative agent, to produce sleep, to equalize the circulation, and to relieve the condition of nervous irritability commonly called nervousness, no drug is more useful than bromide of sodium. This salt is preferable to the other bromides because it is less unpleasant to take, and is less irritating to the stomach, while at the same time it is not inferior in therapeutic value. In prescribing this very valuable drug, one should never forget that it does not increase the strength or nutrition of the nervous system. It should not, therefore, be relied upon for continuous prolonged administration to the exclusion of other remedies. On the contrary, its use should be supplemented by the administration of general tonics and of special nerve tonics. Iron and arsenic are especially well adapted for this purpose.

"In conclusion, the following propositions are presented:

"1. At the time of life when the menopause occurs the various organs of a woman's body are likely to be in a state of depression as regards either their nutrition or functional activity, so that the normal equilibrium of healthy action may be easily disturbed, and abnormal action, the manifestation of disordered function, may be inaugurated and perpetuated.

"2. The cessation of menstruation is an event of great physiological importance, and is perfectly competent to produce grave disturbances of the nervous system, if any predisposition to them already exists.

"3. The more common disorders of the nervous system occurring under these circumstances are functional in character, and are associated with disturbances of functions of other organs, and especially of the digestive, circulatory, and hematopoietic systems.

"4. In their treatment, attention should first be paid to improving the general nutrition of all the tissues of the body, and restoring each organ to its normal activity.

"5. If, after all the other organs have resumed the proper performance of their functions, symptoms referable to a disordered condition of the nervous system still persist, recourse must be had to remedies which act directly upon the nervous system, either by improving its nutrition or by modifying and regulating its action."

A Newspaper Tirade against Medicine.—Nowadays it is rare to encounter such venom and such dense ignorance as are displayed in the following editorial article, entitled *Foes to Progress*, which appeared in the *Saint Paul Daily Globe* for September 10th:

"The recent session of the world's medical congress at Washington, if remarkable for nothing else, was remarkable as a display of the ignorance that exists among physicians of the human system, the ills that afflict it, and the proper remedies for those ailments. Disease was discussed in all its thousand forms, and remedies for some afflictions were suggested, but it is a little singular that in no instance was any remedy for any given disease recommended, save as an experiment.

The doctors were honest enough to admit, tacitly, at least, that they had no specific in the entire materia medica for any given complaint. Some drugs were found to have a specific action in a few instances, but utterly failed of producing the desired results in others. The most that could be done was to advise that physicians experiment with this or that drug. It might cure the patient, but no guarantee was given that it would not kill him. Nothing could more thoroughly explode the notion that medicine is a science than the confessions of the doctors assembled at Washington.

"Of all the so-called learned professions, that of medicine is the least progressive. There exists in the mind of every graduate of a medical college an overpowering dread of innovation. The remedies of a hundred years ago are the remedies of the present time, and the mode of administering them is substantially the same. Innovations are frowned upon by 'the fathers,' and progress is denounced as empiricism. The discoverer of a new remedy is denounced as a quack, and all countenance is withdrawn from him. The physician who tramples upon the traditions of the profession treads upon the corns of every other practitioner, and if he persists in discarding text-books that have grown musty with age, and precedents that were established in a by and forgotten era, he is expelled from association with his fellows. If he makes a discovery of value to suffering humanity, he must use it in secret, for if he thinks to benefit mankind by divulging it, he is confronted by the inexorable fiat of his fellows—the ethics of the profession"—and sooner than suffer ostracism he concludes that it will be wise to join the procession—a procession that never moves, but is rooted in prejudice, bound securely by precedent and tradition, and is scarcely within hailing distance of the present century.

"Meanwhile the march of disease and death is on. Every year new diseases and new complications of old diseases manifest themselves. Remedies are sometimes found, and if they are consistent with the practices of the past they are adopted. If, however, they are repugnant to precedent, the patient dies, for few physicians have the hardihood to apply a new remedy. The cholera, the yellow fever, scarlet fever, and diphtheria have been carrying off thousands of victims every year for generations. They are almost as fatal to-day as at any time in their career, for no remedy has been found and applied. They have been somewhat mitigated in severity by the observance of sanitary and hygienic precautions, but these have not been at the suggestion of the doctors. The grip comes around periodically, and, although tens of thousands have fallen victims, the doctors confess themselves powerless to combat it. Their experiments result in nothing of benefit; their diagnoses differ; their remedies are applied in a haphazard, hit-or-miss manner, and the undertaker gets a job. Scarlet fever is taking on new aspects of late years, caused, doubtless, by changes in the manner of living and in natural conditions. The treatment, however, remains the same—as inflexible as the laws of the Medes and Persians. Diphtheria is growing alarmingly prevalent and fatal. The remedies applied seldom reach the seat of the disease, and the patient only recovers if he is so fortunate as to have an extraordinary constitution.

"And so it goes. Disease strides far faster than those who combat it. Medical colleges increase rapidly, and grind out doctors by the score, each batch less skillful and less progressive than its predecessor. Humanity suffers, but the ethics and traditions of the profession must be maintained."

An esteemed correspondent who sent us this gem says of it that it is evidently a comment on the Pan-American Medical Congress, although the writer calls it the World's Medical Congress, and adds that "one would judge that the writer had failed in introducing some pet patented or proprietary remedy or instrument at the congress, and had 'got it in for' the entire medical profession."

Organic Juices as Remedies.—In the August number of the *Indian Medical Record* there is an editorial article in which, after giving a résumé of recent investigations in the therapeutic employment of organic juices, the writer says:

"It is hard to conceive that these preparations from organs can prove curative in organic lesions. It is quite reasonable to expect that they are *palliative* in their action in such cases; and that in impaired functional activity of organs their effects are permanent and

curative. We can admit, as Dr. Hammond lays down, 'that all the organs of the body possess the power, when in a state of health, of secreting from the blood the peculiar substance that they require for their nutrition, and that they take this substance and no other, never making a mistake in the matter.' These vaunted preparations, then, may supply the functionally deranged organs with their peculiar pabulum, or help to furnish the general economy and organization with whatever these organs, when diseased, are unable to provide it. But even for such functional restoration and such amelioration of distressing conditions in incurable organic ailments that these new preparations from organs evidently effect, the thanks of the profession are due to the experimentalist in this new field of research. We may remark *en passant* that it has been our experience that the liver of the sheep, which forms an ordinary article of food, acts as a mild aperient and increases the biliary secretion if partaken of in quantities of about half a pound in any of the ordinarily made dishes."

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Contributors who wish to order REPRINTS of their articles should do so on a blank prepared for that purpose, which will be sent to them by the publishers on receipt of a request to that effect. The order should be sent to the publishers, and not to the editor.

Original Communications.

SANITARY NOTES AND BEAMS.*

By ALBERT L. GIHON, A. M., M. D.,
MEDICAL DIRECTOR, UNITED STATES NAVY.

"And why beholdest thou the mote that is in thy brother's eye, but considerest not the beam that is in thine own eye?"—St. Luke, vi, 41, 42.

THESE words of the Teacher of Humanity, which "the beloved physician" of the first century has recorded, are an appropriate text for the opening address in the important session with whose conduct I have been charged in this congress.

Time was—and that no long time—when Hygeia, the neglected Cinderella of the medical family, slunk unnoticed among menials; now that she graces the *salon*, her proud sisters caress her and suitors court her favor. As an old admirer of this fair mistress, whose colors I have worn through youth and manhood, I may be pardoned the personal exultation that I have lived to see her suzeraine.

The ascendancy of hygiene has greatedened and glorified medicine, without dimming the luster of any other branch; but though her cult is established, her mission has not ended with the recognition of her supremacy and the faithful following of her own ilk. To-day she turns to the people and their rulers, outside the medical fold, and demands the place in their councils that is hers of right. A makeshift share in the administration of the sanitary interests of the country has been grudgingly allowed, but the inexorable demands of modern enlightenment can not be satisfied until the conservator of the public health shall sit a peer among the rulers. The minister of war may build mighty engines for destruction and defense and muster vast armies and navies, which disease can disperse with a weapon so tiny that the eye can not discover and no mere military expedient antagonize. The minister of finance may fill his treasure houses with gold and silver by the ton, which can buy human souls honor, virtue, independence, everything but the boon of health, God's free gift to man, through which alone he can be like his own glorious image. Commerce, agriculture, manufacture, fishery, mining, and all the industrial occupations of the human race, which are now the objects of the intelligent supervision of cabinet ministers, who are grand masters of political economy and social science, can not thrive without vigor of human blood and brains and brawn, which are the machinery of these occupations; yet until this decade it has not been thought that the intelligent supervision of a grand master of the divine science of medicine was necessary to preserve this vigorous health of the community, without which even these other ministers can themselves only imperfectly perform their own offices of administration.

When I entered the service of the Government of the

United States as an officer in the Medical Department of the Navy, nearly forty years ago, with a minimum of experience and a maximum of enthusiasm and an exalted opinion of the dignity and responsibility of my charge, which a lifetime has only intensified, I was astounded at the total ignorance of sanitary provision then prevailing in the naval service. Medical officers were curtly reminded that their opinions and advice would be asked when desired; their protests at acts that filled the hospitals and mortuary lists were contemptuously unheeded; they were reproved for officiousness and punished as insubordinate; disabled sailors and marines were discharged and their places and those of the dead were filled without regret or remorse, but with the shameless boast that "if men die we can ship others," like the *Netherland commodore*, some of whose crew had been killed by the careless firing of a shotted saluting gun, who accepted the apology for the accident with the nonchalant remark, "Dere are plenty more Dutchmens in Holland."

The battleships and cruisers of modern navies are not more unlike the brigs and sloops of war of forty years ago than are the cleanly, well-fed, comfortably clad and cared-for enlisted men, who go on shore daily, subscribe for newspapers, and write letters—a different race from the begrimed and degraded "shell-backs," who were ordered to their work with curses and punished with brutality for offenses which neglect and ill-treatment had incited. The naval and military establishments have considered the beam in their own eyes, but civil authorities are still purblind to the necessity for organized intelligent sanitary supervision and direction, and grope for succor only under the flashlight of a pestilential visitation. The following from a recent editorial in an influential journal is pertinent: "Whether cholera has or has not made its appearance at Chester, which is practically one of the suburbs of Philadelphia, it is certain that the conditions reported to exist there are in the highest degree favorable for the introduction and spread of that disease. All accounts represent the neighborhood in which the alleged cases occurred as filthy beyond description and occupied by a class of persons who pay no attention whatever to the laws of health or personal cleanliness. Of course, the country now has the pleasant assurance that the place is to be thoroughly cleaned and effectively quarantined; but why were not the steps necessary for the protection of the public health taken before the resulting disease, whether cholera or not, had gained such a footing that already five persons have died from it? The time to lock the stable door is before the horses housed therein are stolen, and the way to treat contagious diseases is to prevent their appearance and not wait for them to gain a foothold and then try to stamp them out."

The Secretary General has announced that the proceedings of this section and its congener, the Section in Marine Hygiene and Quarantine, will constitute a special feature of this congress. It is therefore incumbent upon us before adjourning to declare very positively the opinion of the members of this section, experienced practical sanitarians.

* The presidential address read before the Section in Hygiene, Climatology, and Demography of the First Pan-American Medical Congress.

rians from every country of the Western Hemisphere, that the interests of the public health must be intrusted to a department of the Government especially charged with their administration, with equal independent executive authority as given to other national departments. Temporalizing legislation under the spur of emergencies does not befit this age. As the enlightened physician seeks to prevent his charges becoming ill, so should the guardian of the public health be able to forestall these emergencies, whose pecuniary cost, in money expended and wasted, in trade paralyzed and diverted, in labor and its wages lost by the sick and terrified and dead, in a single epidemic, exceeds that of maintaining an efficient sanitary service for the whole country for a whole year.

The fault of the medical profession has always been its lack of bold assertion of its rights; but it can no longer hesitate to declare to trade and commerce and agriculture and manufacture that the health and vigor which are essential to prosperity can not be secured by their own unskilled, uninformed efforts. They must learn, as the military services have learned, that powerful armies and navies are the results of able and untrammelled medical departments. It is as unwise to confide the care of the national health to a financier, however astute, as to expect a postmaster general to understandingly control a bureau of agriculture, or a fishery commissioner to best administer the affairs of the public schools, and an attorney general to direct the mining industries. The health of a nation is a national consideration involving international co-operation. There should be no priority nor clash of sectional interests. State lines are not respected by epidemic intruders. No State barrier can be so defensive and impenetrable that the toxiferous germ can not pass through. The precise form of administration may be left to legislation, the indispensable requisites being that it shall be national, that it shall have parity of voice and influence in the national councils, that it shall have independent executive authority under the limitations common to other departments, and that it shall be intrusted to educated and experienced medical men, who alone are competent to assume its responsibilities.*

I have not wandered from my text in thus pleading for a national public health establishment. Spasmodic tentative provisions in emergencies are nothing but attempts to discover *motes* from abroad when the *beams* at home should first receive consideration. To parallel further and in another sense, the scientific tendency of the day is literally toward mote hunting through microscopes instead of using our human eyes upon visible abominations. The sanitarian, official or amateur, need only look about him to be appalled at the spectacle of indifference of rich and poor, high and low, to dangers far greater than any from cholera microbes, which confront them every hour, and it may

be worth our while to indicate some of these beams in our own eyes, which we complacently refuse to see, while we magnify the motes on our horizon.

The preventable disease, which kills more of the human race than cholera and yellow fever together and in its ordinarily slow process of killing, lessens the productive power of a community, directly by the enfeeblement of its victims and indirectly by its demands upon members of households and eleemosynary institutions for the care of these chronic invalids. Tuberculosis is tolerated with as little concern as the Mongolian exhibits for small-pox or the creole for yellow fever and malaria. The consumptive, whose traits no professional acumen is required to recognize, frequents our crowded thoroughfares, sits beside us in unventilated street cars and at the hotel table, occupies Pullman sleeping berths, and shares the steamship stateroom, wholly unrestrained and innocently ignorant that he or she may be sowing the seeds of disease among delicate women and children. Any one may verify this who uses his eyes for the purpose along the railway and coastwise steamer routes to our invalid resorts. Within a twelvemonth, on my way to Mexico by rail, I was fellow-passenger with two invalids in the advanced stage of phthisis, *en route* for San Antonio, one of whom occupied the opposite berth and the other one diagonally across the car, so that I could see and hear them coughing and expectorating, with only such attention as well-intending but unskilled relatives could render. They had no vessels for receiving their sputa, which were discharged in their pocket handkerchiefs to be scattered over pillows, coverlets, and blankets. They left the car in the morning, and I saw those same berths—it is true with change of linen sheets and pillowcases, but with no change of blankets, mattresses, or pillows—occupied that very night by other travelers, who were thus subjected to contact with a pathogenic microbe far more tenacious of life and power of evil-doing than the dreaded cholera spirillum. One has only to sit in a crowded street car on a winter day and watch the clouds of respiratory steam circling from the mouths and nostrils of the unclean and diseased into the mouths and nostrils of the clean and healthy, as the expiratory effort of the one corresponds with the inspiratory act of the other. The road is short but straight and sure from vomica and mucous patch to the receptive nidus in another's body. Who that has ever had forced upon him an aerial feast of cabbage, onions, garlic, alcohol, tobacco, and the gastric effluvia of an old debauchee can doubt that aqueous vapor can transport microscopic germs by the same route? Not long ago I traveled by sea from New York to Charleston, and for two nights was cabin with some twenty consumptives going to Florida. The air was chilly and they huddled around the stoves and fearfully and fearlessly closed doors and windows until the atmosphere became stifling and surcharged with their emanations and the dried sputa, which they ejected on every side. It was comparatively easy to escape during the day by staying on deck, and I slept with my stateroom windows wide open, but the curtains, carpets, pillows, and mattresses had been saturated by I know not how many expectorating predecessors. I have visited fifty small-pox

* These propositions were unanimously adopted in the form of a resolution in these terms by the conjoined Sections in Hygiene, Climatology, and Demography, and in Marine Hygiene and Quarantine, and reported to the general session of the congress, by which it was referred to the International Executive Committee, which returned it with its indorsement and direction that it be transmitted as the voice of the congress to the executives of all the countries represented therein.

cases a day, have gone through yellow-fever wards, and stood by cholera bedsides with far less apprehension than I experienced on that trip, yet it was one taken by many thousands of people, who would have been terrified to know that there had been a case of cholera within a mile to leeward of their homes. Recall in your several experiences the instances of members of a family who have occupied the same chamber and bed with a gentle and beloved aunt or sister, and those of tuberculous husbands or wives, who have become ill like them with pulmonary phthisis attributed to everything but the manifest cause.

In former years I preached a crusade against another virulent communicable disease, in the interest especially of innocent and helpless women and children, and for a time I was gratified to find that husbands and fathers began to realize, from the numerous indisputable instances of innocent infection I was able to report, that syphilis might be, as it had been, contracted from combs and brushes and rough-edged drinking vessels in hotels, sleeping cars, and boarding houses, from pens, pencils, and paint brushes that had been held between diseased lips, from dirty old bank notes, from street-venders' toys, from a lover's kiss, a stranger's caress, or a nurse's ministrations. Supported by an array of cases of infected children, young girls, and elderly men and women, the committee of the American Public Health Association, of which I was chairman, advocated the enactment of a law placing venereal disease in the category of other communicable affections and punishing its transmission as a misdemeanor; but there were too many of the self-righteous blind to these beams in their eyes, who thought it wiser to seek to exterminate by ignoring its existence and never uttering the name of a disease that has done more harm to mankind than all the diphtheria, typhoid, small-pox, measles, and scarlet fever which are so carefully isolated and their statistics so regularly collected and promulgated—a disease that travels with the missionary to Asia, Africa, and the Pacific, and decimates bodies faster than he can whiten souls.

I do not expect that all who have eyes will see as I do, or, having ears, hearken to what I say. The idle and perverse generation of the first century will have its following in the twentieth, and men and women will continue to do the insanitary things they ought not to do, and leave undone the sanitary precautions they ought to take, despite our warning, our imploring, our advice, or our denunciation. However benevolent and beneficent the hygienist's aim, his unappreciated, unrequited, and often unprofitable labor is enough to deter him from what has been derisively described as only an effort to procure the survival of the unfit, and thus thwart Nature's own attempt to rid the world of them. He encounters another obstacle to success as aggravating as the disbelief in the necessity for his work. The authorities listen to his warnings, and then employ their own perfunctory and superficial methods of protection. Told that absolute cleanliness is the fundamental fact of sanitation, street cleaners are set at work brushing the surface dirt into little heaps, which passing vehicles again distribute, or the winds carry into the open windows of adjacent residences. The refuse of the house-

hold is deposited in vessels on the sidewalks of crowded thoroughfares to be emptied after a time into collecting carts, from which clouds of dust envelop passers and circulate back into the houses—*living* dust, for Manfredi found an average of 761,521,000 microbes to the gramme of the street dust of Naples, from which he cultivated pus, malignant oedema, tetanus, tubercle, and septicemia. Swarms of flies feed on the decomposing contents of exposed garbage pans and buckets, and carry their tiny germ-laden booty into the butcher shop of the poor and the kitchen of the millionaire. Who can dispute that if the hair of a Newfoundland dog could transport yellow fever to a distant Mississippi town, and a newspaper printed in an Ohio village where small-pox was raging could fatally infect a United States consul in a foreign port where the disease did not exist, that a cloud of dust, a swarm of flies, or a single fly—*as* Sawtschenko, Simmonds, and Sternberg demonstrate—can disseminate cholera and become a focus of infection, which would have been impossible had ordinary care been exercised in preventing the exposure and promptly destroying the discharges and excreta of those already sick? Cities are reported clean whose sanitary inspectors have merely walked through crowded tenements, a hundred or more a day, and been satisfied with external evidences of brush and broom, leaving carpets and rugs unlifted; pieces of heavy furniture, with the fluff of years behind and beneath, unmoved; and closets, cupboards, pantries, storerooms, attics, and cellars undisturbed. The cellars of our great cities—and I speak with personal knowledge of many in New York, Brooklyn, and Philadelphia—are greater abominations than even filthy living apartments. The *New York Herald* of the 8th of August, narrating the death of two children by falling from a window on the fourth floor of a tenement at 204 West Sixty-first Street, said: "To get at the bodies of her children the frantic mother had to go through the cellar of the house. There she waded through indescribable filth, almost knee deep, to where her children lay, when the foul odors overcame her and she fainted." It added: "The Sanitary Superintendent issued an order that the cellar must be cleaned out within twenty-four hours." Do you believe that it was the only one of its kind that needed cleaning? No city can be accounted clean until its ordinances require every cellar door to be widely opened to sun and air—that royal pair of germicides; every cellar to be emptied of its refuse; every cellar wall and ceiling to be scraped and whitewashed; every cellar floor to be taken up if rotted, and sprinkled with lime if uncovered—a tedious and expensive process; but effective sanitation, costly as it must need be, is cheap beside the outlay of a single epidemic. There are underground foulnesses in all our great cities of which they should be rid at any cost, as where rag-pickers and bone-gatherers collect their filthy stores and Italian street-corner fruit sellers keep their decomposing bananas, grapes, and oranges, till, rubbed off by dirty pocket handkerchiefs, they are exposed for sale, glistening after their repulsive polish with impure saliva. If some mote-hunter, loath to see so huge a beam, chooses to find solace in disbelief, I might be able to shock him by declaring that I have seen the figs he munches unconcern-

edly flattened in their pretty boxes, in a country where syphilis reigns, by questionable thumbs moistened by equally suspicious saliva. Shall I, while revealing insanitary horrors, dare lift the sweeping train of the fair promenader, fashioned after that of women in other countries who never walk upon the streets, and show the nasty mess of spittle, excreta, mud, and dust she gathers from the sidewalks upon her white skirts and silk stockings? She will not believe me; but the bacteriologist, who scoops the mud from between the cobblestones of the streets to find it swarming with microscopic life, can gather as rich a harvest of microbes from these same dainty undergarments.

Nor are these the only beams we overlook in our search for motes. Dr. Graham, bacteriologist of Starling Medical College, in response to an official inquiry by a member of Congress, reported that he was able to obtain thirteen colonies of two kinds of bacteria from one dirty, worn bank-note, and the *Medical Record* of January 21st of this year states that a British bacteriologist discovered nineteen thousand microbes, including those of tuberculosis, diphtheria, and scarlatina, vegetating upon a single note.

Other harborers of morbid germs are the textile fabrics employed in the furnishings of street cars and stages, which the chairman of the Sanitary Committee of the New York Board of Health reports as "a menace to public health by reason of their continual exposure to uncleanness and infection from the clothing of diseased and filthy passengers," which, like their grimy bodies, may be foul with the sputa of diphtheria, tuberculosis, or syphilis, the desquamations of scarlatina, measles, or erysipelas, the emanations of typhus, or the alvine discharges of cholera or dysentery. A commendable league of zealous ladies, who are seeking to prevent the abominable practice of expectorating in public vehicles, induced a few car companies to display placards to the effect that "Gentlemen are requested not to spit on the floor," but these appeals intended for beasts, who were never gentlemen, were hung in inconspicuous places or covered by other notices, and the spitters continue to discharge their syphilitic and tubercular sputa on the floor mats, to be taken up on ladies' petticoats and carried to their homes. The spitter and the other beast, who voids his impure nasal secretions where it suits him, are largely responsible for the spread of influenza, for, according to Pfeiffer, the discoverer of its bacillus, "its contagium is found in the moist secretions of acute cases in the discharges from the nasal and bronchial mucous membranes."

Further detail would be out of place in an introductory address to this section. Let it suffice to point to the fragile spirillum of cholera which we are exorcising by "bell, book, and candle," as illustrating the dreaded *motes* of my text, and to the sturdy, robust bacillus of tubercle as the *beam* we will not consider. "Cholera," says Ernest Hart, "can only be drunk and eaten. It can not be caught and breathed"; but the tubercular mischief-maker, who finds the ever-open door of the respiratory passages his readiest approach, may also enter at any or all the orifices of the body. Among 1,000 autopsies, Osler found 275 with tuberculosis; among 8,873 patients in the surgical clinic at

Würzburg, one seventh (1,227) were tubercular; the necroscopic statistics of Harris and others "show that one third, perhaps over one half, of the people who live to middle age have some form of tubercular infection"; and Dr. Williams, of Johns Hopkins Hospital, estimates that tuberculosis of the female generative organs is four times more frequent than generally supposed (*Medical Record*, March 18th). Can any more obvious method of direct infection in these cases be imagined than the trailing skirts of women gathering tubercular sputa from the pavements?

The sanitary inspector is destined to become the most important agent of future civic administration. The perfunctory burning of a pan of sulphur in a diphtheritic chamber, the sprinkling here and there of a solution of corrosive sublimate, or the substitution of the sweeter scent of thymol, pinol, or some newer "ol" for the foul odor of the privy, will not then be the tolerated limit of his interference. All that science teaches and all that intelligence can devise will be exacted of him. A sanitary inspection will be a deliberate, painstaking, critical examination of nooks and corners and their disinfection, the flooding of the lairs of microscopic motes, and the deluging of unsightly beams with those unstopped, unpated, inexhaustible germicides—air and sunshine.

Coincident with the approaching Eleventh International Medical Congress at Rome, and its fitting complement, there is to be an exposition of medicine and hygiene, and significant of the share accorded sanitary science in a medical congress representing the highest modern professional attainment, it will be noticed that of the *ten* classes which, in their *ensemble*, make up the exposition, *five* are exclusively hygienic—to wit, (4) plans, models, and *matériel* bearing on school management and sanitary civic organization (*riordnamento urbano*); (6) plans, models, and *matériel* for hygienic constructions; (7) apparatus and furniture for hygienic uses in the interior of common dwelling-houses and public offices on every scale; (8) *matériel*, appliances, and accommodations for the practice of personal hygiene; and (9) plans, models, and appliances for the hygiene of the working classes. Three are partly hygienic—to wit, (1) apparatus, *matériel*, and plans of buildings for scientific and technical investigation in therapeutics, biology, and hygiene; (3) articles and appurtenances requisite in salvage service and in *assistance publique*; and (10) books, atlases, photographs, and such like recently published and having reference to the medical, biologic, and hygienic sciences.

Two only of the *ten* are exclusively medical and surgical, to wit:

(2) Apparatus, instruments, and *matériel thérapeutique* in the various departments of medicine, and (5) plans, apparatus, and furniture for the purposes of the divisional surgeon in cities. Additional to these, special classes are devoted to hydrology and balneotherapy, and to the Italian Red Cross Society, both of which are practical outcomes of sanitary endeavor.

I do not forget that climatology and demography, as well as hygiene, are within the purview of this section; but what are climatology and climatotherapy but applied hygiene, and what demography but the demonstration of the

results among masses of people of sanitary or insanitary conditions? The climatologist is of necessity a hygienist. The *Materia Medica* and *Pharmacopœia* are not his text-books. Physical geography, meteorology, hydrology, balneology are his scriptures and gospels; the vivifying light, invigorating air, and healing springs and waters his armamenta—his anodynes and hypnotics, his roborants and eutrophics, his alterants and excrements. The high professional standing of the American Climatological Association, one of the constituent bodies of the Congress of American Physicians and Surgeons, and the distinguished climatologists who are with us to-day and who are conspicuous in every international congress of hygiene, are evidences of the place in medicine of climatotherapy, the practical end of medical climatology—that broad specialty which robs so many graves of untimely victims and makes so many, heretofore without hope, able, if not to take up their beds, at least to get out of them and walk. The field of the climatologist is as broad as the habitable surface of the globe—in the high altitudes of Colorado and the Alps; in the odorous pine forests of Norway and the Carolinas; on the seashore or upon the wide waste of waters and their islet oases swept by ocean breezes.

Our American vital statistics are not yet piled high enough to form the foundation for a substantial superstructure of demography. The great caldron in which we are mixing Celts and Saxons, Semites and Aryans, with a seasoning of syphilis, tuberculosis, and insanity, is simmering with what ultimate homogeneity can only be conjectured. When immigration was a tiny stream, however muddy and noisome, poured into a rapid river of pure water, it was soon lost in the crystal fluid; but now that huge sewers are discharging their fetid pestilential torrents into a placid lake that has no outlet, the lake itself becomes turbid and unclean. Already in the *culs-de sac*, which are nearest the open mouths of these foul sewers and receive their floating scum—the prisons, reformatories, almshouses, insane asylums, and hospitals—this filthy, debased, and diseased foreign element is ascendant, and our demographers have a simple task in representing its volume by numerical statistics. Dr. Frederick H. Wines, the distinguished compiler of this portion of the census of the United States for 1890, demonstrates by the indisputable evidence of figures that while the foreign-born constitute only seventeen per centum of our total white population—in round numbers about one sixth—yet they furnish over half of all the paupers in the almshouses of the country. It is evident that the traits of the Saxon are disappearing from our national complexion, and if the proper solution of the negro question be, as suggested by certain prominent Afro-Americans, to bleach it out by admixture, we may expect the hue of our descendants to be decidedly tawny.

The most zealous demographers of this decade are the French, who have been spurred in their statistical researches to discover the causes of the too evident depopulation of France of its native races; but are we not again refusing to consider the beam in our own eyes in not giving heed to the operation of similar conditions in our own country? Dr. Billings announces that our birth-rate has

fallen from thirty-six in a thousand inhabitants in 1880 to thirty-one in a thousand in 1890. The twenty to thirty children of our ancestors, the dozen or more of our great-grandmothers, have dwindled progressively to five or six, then to three or four, until to-day one or two or none represents the fecundity of the educated classes. *The Independent*, referring to New England Puritan life, says: "Large families abounded. According to Cotton Mather, one woman had twenty-two children and another twenty-three by one husband, and a third was mother to seven-and-twenty. Sir William Phipps was one of twenty-six children of the same mother. Printer Green had thirty. The Rev. John Sherman, of Watertown, had twenty-six children by two wives, the second spouse the mother of twenty. The Rev. Samuel Willard, first minister of Groton, had twenty children, being himself one of seventeen, as was Benjamin Franklin." The paragraphist who can now record the case of the woman of thirty-one at Cold Spring, who has become the mother of seventeen children in nine years, or that of the Georgia matron of twenty-five who rejoices in thirteen, has, in newspaper parlance, "a great find." The spectacle of impending maternity among our better classes is becoming more and more rare, and still more rare that of an infant nursing at its mother's breast. Only in the squalid quarters and *bantieux* of our great cities, where the English language is not spoken among imported lazzaroni and the overflow of European ghettos, does the process of human incubation go on as God and Nature intended. The laws of creation are immutable, and one has only to look beneath the disfigurement of female dress to recognize the evidences of imperfect physical development—in stooping, unsymmetrical shoulders, in meager limbs, in narrow pelves, and flattened busts. Dr. Otis exhibited at the recent meeting of the American Climatological Association, in illustration of diametric measurements of the thorax, the profiles of a number of female chests, which were supposed to be those of little girls, until he explained that they were the contours of nubile young women in Boston normal schools, like her whom Solomon bewailed in The Song of Songs: "We have a little sister, and she hath no breasts: What shall we do for our little sister in the day when she shall be spoken for?" My friend, Dr. Robert T. Morris, of New York, has significantly called attention to the fact that eighty per centum of all Aryan American women have rudimentary clitorides, and he asks if evolution is trying to do away with this organ in the degenerative changes characteristic of highly civilized varieties of the *Homo sapiens*, of which early falling hair, decaying teeth, weak mammary glands, and badly balanced eye muscles are other examples. Is the sexual instinct losing its potency as a maternal factor? Is marriage only a social office for the display of finery on the brides and bridesmaids and the entertainment of crowds of gaping strangers? Is the virgin wife best prepared for conception by months of preliminary surexcitation and feverish anxiety, and is a fatiguing railroad journey the best prelude to an act which should lead to the inception of a human being—the incarnation of a human soul? Has the function of reproduction come to be regarded only as a bestial and un-

desirable concomitant of matrimony, and lactation its vulgar, indecent supplement, and is all this attributable to physical deterioration shown by the undeveloped or imprisoned *mentula muliebris* and atrophied mammae, and how far is this the explanation of the diminished fecundity of the Aryan American woman? These are problems as interesting to our demographers as the depopulation of France, the disappearance of South Sea Islanders, the migration of Semitic and Mongolian races, and the effects of malnutrition of indigenes of Ireland and Russia.

But, gentlemen, I shall no longer trench upon time that belongs to you. I am highly gratified at your presence and thank you most cordially for your kind attention.*

SEÑORES, AMIGOS Y COLEGAS DE FUERA: Permitidme daros la mas cordial bienvenida á nuestra capital, á nombre de los miembros de los Estados Unidos de esta Sección.

El largo viaje que habeis hecho para venir á esta ciudad, demuestra el gran interés que os inspira este acontecimiento. De tal y muy importante puede considerarse el hecho, de que por primera vez en su historia, se halle reunida la profesión médica de toda la America en un gran congreso.

Hacen como unos nueve años que algunos Sanitarios Canadenses, reclamaron el derecho de que como Americanos les asistía á ser miembros de la Asociación Americana de Salud Pública y yo, en mi capacidad de Presidente

que era de aquella corporación en aquel entonces, tuve el privilegio de admitirlos como tales.

Las actas subsiguientes de la asociación, demuestran cuán fieles han sido estos miembros á las tradiciones de aquella, con cuanto celo han participado de sus trabajos y cuán dignamente han llenados sus mas altos empleos. Dos años mas tarde se llevaron la asociación á Toronto en su propio territorio.

En 1890, dos distinguidos representantes del Consejo Superior de Salubridad de nuestra hermana la República de Mexico, vinieron á Charleston; y á fuer de Americanos tambien, llamaron á las puertas de la asociación, volviendo al siguiente año en tan crecido número y con una invitación tan cordial de su Gobierno á que nos reunieramos en su propia capital, que fue aceptada su invitación y el *meeting* mas prospero de la asociación—el vigesimo de su historia—se celebró en la antigua Ciudad de los Toltecas.

Hoy en la lista de los Estados representados en el congreso consultivo de la asociación, se hallan fraternalmente unidos, Illinois, Massachusetts y Tennessee, Ontario, Quebec y Manitoba, Guanajuato, Querétaro y Zacatecas.

Lo que han hecho los sanitarios en aquella asociación, que despliega los escudos de los tres paises que la constituyen reunidos, trata de hacer este congreso en favor de toda la profesión médica del Hemisferio Occidental, uniendos sus miembros en una hermandad, cualquiera que sea su raza ó idioma y bien que habiten en las heladas costas del mar Artico ó en las laderas de las colinas de la Tierra del Fuego, entre las montañas de hielo de la Groenlandia, en el archipelago de las Antillas ó en medio de los jardines perpetuos de Hawaii.

Compañeros de toda la America, sed bienvenidos á esta *vuestra capital*, que en el lenguaje mas dulce que es capaz de articular la lengua humana pongamos á vuestra disposición.

THE IMPORTANCE OF PHYSIOLOGICAL CHEMISTRY AS A PART OF MEDICAL EDUCATION.*

By R. H. CHITTENDEN, Ph. D.,

PROFESSOR OF PHYSIOLOGICAL CHEMISTRY
IN THE SHEPHERD SCIENTIFIC SCHOOL OF YALE UNIVERSITY.

In this age of progression, when the attention of the medical profession is being directed toward a broader and more comprehensive system of medical education, it is well to consider some of the claims presented by physiological chemistry to occupy a prominent place in the medical curriculum of the day, or, if not as an integral part of medical study itself, as a fundamental part of that preparatory training which all progressive minds in the medical profession consider as so important for the most complete and intelligent understanding of the science of medicine in its broadest sense.

There can be, I think, no objection from any quarter to the general statement that the study of biology, together with chemistry and physics, constitutes the best and most

* Read before the Section in Pedagogy of the First Pan-American Medical Congress, September 5, 1893.

* The remainder of the address was delivered in Spanish, of which the following is a translation:

GENTLEMEN, OUR FRIENDS AND COLLEAGUES FROM ABROAD: Permit me, on the part of the members of this section from the United States of America, to tender you a most hearty welcome to our capital. Your long travel to this city bespeaks your interest in the occasion. It is no light boast that here, for the first time in its history, the medical profession of all America finds itself united in one great congress. It was about nine years ago that a number of Canadian sanitarians claimed the right as Americans to become members of the American Public Health Association, and it was my privilege as president of that body to receive them as such. The subsequent transactions of that association show how loyal they have been to its traditions, how zealously they have participated in its work, and with what dignity they have filled its highest offices. Two years later they carried the association into their own territory at Toronto.

In 1890 two distinguished representatives of the Superior Council of Health of our sister republic of Mexico came to Charleston, and as Americans likewise knocked at the door of the American Public Health Association, returning the following year in such numbers and with such a hearty welcome from their Government to meet in their own capital that the invitation was accepted, and the most successful meeting of that association—the twentieth in its history—was held in the ancient city of the Toltecs. To-day the roll of States represented in the advisory council shows Illinois, Massachusetts, and Tennessee, Ontario, Quebec, and Manitoba, Guanajuato, Querétaro, and Zacatecas in one fraternal union.

What sanitarians have done in that association, which bears the escutcheons of its three constituent countries side by side, this congress aims to accomplish for the whole profession of medicine in the Western Hemisphere, uniting its members in one brotherhood, whatever their race or language, and whether their homes be on the frozen shores of the Arctic or the hillsides of Tierra del Fuego, among Greenland's icy mountains, in the archipelago of the West Indies, or amid the perennial gardens of Hawaii.

Physicians and brothers from the United States of all America, welcome to this your capital, which, in that sweetest language spoken by human tongues, pongamos á vuestra disposición.

natural line of preparatory work for the medical student. Indeed, it may well be questioned whether physics, chemistry, and a certain amount of biology should not form a necessary part of the training of any person seeking a liberal education. To be sure, the intending medical student may well pursue these subjects much more thoroughly than one who desires general training rather than special knowledge. The biological sciences, however, so closely underlie the science of medicine, are so plainly the substructure on which the latter rests, that one can hardly conceive of a broad and intelligent comprehension of the subject without a preliminary training in some one or more of the biological sciences.

Just here, however, in order to prevent any possible misunderstanding, let me at once emphasize the fact that what is required first of all of a medical student, as well as of a student in any department of learning, is a broad and well-developed mind, trained to habits of thought and observation, endowed with the power of logical reasoning, and fully alive to the necessity for broad and liberal culture. This is obviously the first requisite, and it is folly to assume that a limited biological training, although valuable in itself, can counteract the defects or make good the deficiencies incidental to the lack of intellectual development. A boy fresh from the district school or from the high schools of our cities, with his mind mostly unformed, is fit neither for the study of medicine nor for that of any other profession. What he requires first of all is mental training. We need not discuss here whether such training should be obtained through classical studies or through mathematics and the natural sciences. It is sufficient for present purposes that the need for general training be widely recognized. Let it be understood that the medical profession demands men of high intellectual attainments, broad and scholarly, and that there is no short road of preparation for medical studies, through biological or other channels, any more than for the professions of law, theology, art, or literature.

Granting all this, as every one interested in the future development of medicine must, we come back to our starting point—viz., that biology constitutes one of the most important, if not the important, preparatory study in medical education. Biology treats of the science of life, of the structure and function of living organisms high and low in the scale. What more natural and appropriate, therefore, than that the student aiming to make his life work the study and treatment of the diseased human body should turn to the study of animal and vegetable forms in order to gain knowledge and experience of the general laws regulating life in all its phases? It is only by a close scrutiny of the simpler forms of life that we obtain the requisite knowledge to unravel the complexities of structure and function characteristic of the more highly developed human organism. The broad line of demarcation formerly drawn between the life processes of animals and plants has been gradually growing narrower and more indistinct until to-day we are forced to believe in the existence of essentially the same kind of protoplasm (*i. e.*, containing essentially the same chemical substances) in animal

and vegetable cells alike, and without regard to the position they occupy in the scale of life, whether in man or in the highest or lowest animals and plants. This naturally leads to the view "that definite fundamental chemical formations and changes are common to all living beings"; and although there are many superficial as well as fundamental differences between the different classes and orders of animals and plants, yet it is evident "that many processes can take place according to a conformable fundamental type. Further in the life processes of man these parallels are again found, whose simplest manifestation we perhaps follow with the least difficulty in the lowest organisms. We are thus brought to a definite unity in the original structure and processes of living existence."* "All living beings, of form and life-phenomena the most widely different, appear to owe their fundamental structure to an original chemical organization, with properties common to them all," from which we can see direct gain to the medical student in the study of lower forms of animal and vegetable life.

Further, as an indirect gain, it must not be overlooked that in such lines of biological inquiry the student, while acquiring a fund of useful information more or less directly applicable to his every-day needs, undergoes a training the value of which can not be overestimated. His powers of observation are called into play, the habit of drawing deductions from observed facts, the noting of resemblances and differences, all tend to educate him in methods of exact work and lead eventually to habits of self-reliance and a freedom from prejudice and preconceived opinions which will prove of inestimable value in his after-life of practice by the bedside. He learns to appreciate the significance of small things, and becomes thereby well trained in the essentials of accurate diagnosis in a manner which can not be imitated by text-book instruction in any branch of knowledge. He must be taught to observe, and to observe accurately; and being possessed of reasoning powers, soon acquires the habit of close and logical reasoning.

All this, I take it, will be readily granted by the unprejudiced mind, but the question naturally presents itself here as to what is meant by or included under the term of biology. We need not stop for a scientific definition of biology, for our interest centers rather in the interpretation of the word as applied to biological courses of instruction. Judging from the courses offered by most of our institutions of learning under the head of biology, the latter ordinarily includes more or less zoology and botany, with a comparatively large amount of dissection of typical forms. This is coupled with a certain amount of histology and perhaps embryology, all being intended to constitute a more or less thorough presentation of the morphological side of biology. Less thoroughly presented, ordinarily, is the physiological side. To be sure, physiology is usually found as a part of the curriculum of a biological course, but seldom is it taught other than by text-book or with that degree of thoroughness characteristic of morphological

* Quotations from Hoppe-Seyler's address on the Development of Physiological Chemistry and its Significance in Medicine.

instruction. Further, in those institutions where physiology is given a prominent place in the biological course, it is usually a one-sided presentation of the subject. It consists mostly of muscle and nerve physiology, with demonstrations of blood pressure and kindred experiments designed to illustrate mainly the mechanical side of physiology. I would not be considered for one moment as saying a single word against such lines of physiological experimentation or instruction; it is certainly of the highest importance and, in my judgment, is just what is needed in every course of physiological study. But what I would like to impress upon my hearers is that there is another side of physiology which, in this country at least, has not been cultivated as I believe it should be—viz., the chemical side of physiology, or physiological chemistry. It deals with quite a different series of problems from those pertaining to so-called pure physiology, but I venture to say that the phases of physiological study and investigation it presents to us are as fundamental, if not more so, than any other single line of physiological work.

By physiological chemistry I mean something more than the mere application of chemical analysis to a determination of composition. This, to be sure, is important, but more valuable still is a proper understanding of the processes or lines of functional activity going on in the organs and fluids of the body, a rightful interpretation of which, however, must depend greatly upon our knowledge of the composition of the various parts of the body, and upon the chemical constitution of the many organic substances disseminated through the organism. Physiological function depends largely, if not wholly, upon chemical nature and constitution, and although there is much that is vague and incomplete in our knowledge of the chemistry of the body, it is very evident that such chemical information as is obtainable is a necessary preliminary to all physiological study. Indeed, there is hardly a question either in physiology or in the science or practice of medicine that does not draw to a greater or less extent upon physiological chemistry for its solution. As I am now addressing a body of physicians rather than physiologists, I can not do better than to repeat a remark of Professor Hoppe-Seyler's, taken from an address on the development of physiological chemistry, as illustrative of the important position this well-known authority considers this branch of chemistry should occupy in the medical curriculum. "I can not understand," he states, "how at the present day a physician can recognize, follow in their course, and suitably treat diseases of the stomach and alimentary tract, of the blood, liver, kidneys, and urinary passages, and the different forms of poisoning—how he can suitably regulate the diet in these and in constitutional diseases—without knowledge of the methods of physiological chemistry and of its decisions on questions offering themselves for solution, and without practical training in their application." Again, Leube, the noted clinician, exclaims against the underestimation of physiological chemistry in medicine, and emphasizes the probability that the future success of medicine is dependent mainly upon the advancement of this branch of chemistry. In every medical school in the land there should be

a well-appointed laboratory for the practice and study of physiological chemistry in every direction bearing on medical science. So, too, in every well-rounded biological course there should be ample facilities for instruction and experimentation, not only in pure physiology, but likewise in physiological chemistry, so that a broader and clearer conception of physiology may be obtained than is possible by the presentation of a single side of the subject.

Obviously, in a course of biological instruction, the morphological side rightly receives the first attention; form and structure must be first studied, and thoroughly studied, but chemical composition and function are not to be entirely ignored. So, too, in medicine; the unsymmetrical development, especially of the last twenty years, by which the sovereignty of morphology has been attained, giving undue weight to anatomical methods of investigation, has reached its climax, and the clinicians even are now looking to physiological chemistry to aid them in unraveling many of the hidden processes of life, thus hoping to gain clues to clearer methods of diagnosis and more rational lines of treatment. And yet our medical schools are sadly lacking in facilities for teaching, as it should be taught, this important branch of science. Contrast, for example, the time allotted and the facilities afforded for studying physiological chemistry with the time and facilities given to anatomy, histology, and pathology. The difference is appalling, and I say it with all due respect to the position these three subjects justly occupy in the medical curriculum, and with, I think, a due appreciation of the great gain accruing to medicine from the marvelous development of pathological investigation which has been witnessed during the last two decades. If, however, a small fraction of the time and energy given to these branches of medicine had been devoted to the simultaneous study and investigation of the chemical processes of the body in health and disease, I am sure equally important results would have been obtained, and, as a final outcome, a far more satisfactory explanation of many phenomena for which anatomy, histology, and pathology alone have thus far given only incomplete or unsatisfactory explanations. It is from a judicious combination of the results obtainable by different lines of inquiry that the broadest and most definite, as well as the most accurate, deductions are to be drawn. From the very nature of things, no one branch of biology, no one branch of medicine, is capable of affording as complete and satisfactory answers to the many general questions constantly arising as can be furnished by broader and more comprehensive methods of work.

Let us consider now for a moment some of the reasons for our belief that physiology and medicine are greatly indebted to physiological chemistry for their advancement. Obviously, in the first place, we must remember that our knowledge of the composition of the tissues, organs, and fluids of the organism, whether animal or vegetable, is derived entirely from chemical study and investigation. This is plainly self-evident; but, when we consider how far-reaching are the facts thus obtained in promoting our understanding of the laws of growth of the human body, of the relationships of the various physiologically active

and inactive tissues, of their development, of the character and extent of their activity, and of all the variations incidental to pathological conditions, we see at once the great importance of this knowledge in aiding us to a rightful interpretation of physiological laws.

The great progress made of late years in our knowledge of the various digestive juices of the body, of their mode of action, of the character of the products resulting from the digestion of the various classes of foodstuffs, of the conditions favorable and unfavorable to ferment action—these and many other things connected with the study of digestion in its broadest sense have all been accomplished as the result of long-continued and laborious experimentation in the domain of physiological chemistry—results that have not only helped to give us broader and clearer ideas of the physiology of digestion, but have made possible much of the advance in the diagnosis and treatment of disorders of the alimentary tract.

Take from us our knowledge of the chemical composition of the muscle and nerve tissue, and of the characteristics of the various substances entering into their structure, and what a blank would remain! Consider the importance of our ever-growing knowledge regarding the chemical changes going on in the two master tissues of the body, with their influence on heat production and on proteid and other forms of metabolism, and remember at the same time that, in spite of all that has been accomplished in the past, we have hardly passed the threshold of the possibilities opening up before us.

Then, too, the whole broad question of nutrition in general, with its bearing on health and disease; the study of the urine and feces, with the rich results such study affords as a means of diagnosis; the study of the liver and its secretion, the bile—all are in great part chemical problems, partial solution of which has already afforded results of inestimable value.

Then consider for a moment the part chemistry has played in bringing about our present understanding of the manner in which micro-organisms act in the animal body with its bearing upon the whole question of infectious diseases, the discovery of the production of distinct chemical poisons by specific pathogenic bacteria, with the impetus this fact has given to the search for methods of producing immunity. Then, too, we must not forget to recall the great aid chemistry has lent to therapeutics, not only giving us methods for the preparation of purer and more definite products, but opening up methods of studying the physiological action of drugs which have greatly advanced the growth of scientific pharmacology.

In the brief time allotted for this paper we can not, however, even mention further specific instances of the way in which physiological chemistry touches and strengthens almost every department of medicine. I would that I had time to sketch for you a more detailed picture of this whole matter as it presents itself to my own mind, for I am sure that by so doing it would be possible to impress you more fully with the great need of broader and more liberal methods of instruction in this department of science, both as an aid to a better interpretation of biological

laws and as a necessary part of a *liberal* medical education.

And now allow me to say a word regarding the methods of instruction in physiological chemistry. Happily, the day is past when a medical student is compelled to obtain his knowledge of medicine from lectures or even from books alone. Personal instruction and personal experience in the laboratory are essential requisites in any course of instruction that aims at the highest and best results. So in physiological chemistry there must be a well-equipped laboratory where each student is provided with the necessary space and outfit for demonstrating the fundamental truths of chemical physiology. Instructors, too, must be provided, so that at the most not more than fifteen men shall be under the guidance of one teacher, who shall thereby have time and opportunity to study and develop the material committed to his charge to the fullest extent; for men's minds, as you well know, are not all constructed on the same plan, and personal idiosyncrasies need to be recognized and dealt with in such a manner that each may receive the full benefit of the knowledge and training provided.

A course in physiological chemistry, worthy of the name, should extend at least through six months and preferably through a whole year, with an average of fifteen hours of laboratory work a week, interspersed with lectures, recitations, and demonstrations. Such a course of instruction as I have in mind can be advantageously taken only by men who already have knowledge of general, analytical, and organic chemistry, physics, anatomy, and histology, together with more or less familiarity with general physiology. You say, perhaps, that no medical student can afford to spend such an amount of time on a subject only indirectly connected with medicine. But I believe that to be a grave mistake—one that is in part responsible for the large numbers of half-educated men in the medical profession. As Dr. Billings, in a recent paper in the *Forum* on Medicine as a Career, has well said, "this country is in no need of men possessing the diploma of doctor of medicine; it already has at least twenty thousand more of them than it requires or can properly support; but it does need several hundred, say a thousand, more of properly trained physicians." Eighteen years of experience in a large university in teaching physiological chemistry as a part of a biological course, having for its chief aim the preparation of young men for the study of medicine, has convinced me that the time spent in such study is well spent, and that such a line of work can be advantageously made a part of the university or college curriculum, so that the intending medical student may have a fundamental idea of the scope and aim of physiological chemistry before he enters upon his medical course proper, just as he has, or should have, a knowledge of comparative anatomy, physiology, and general biology.

But the medical school itself can well afford to establish a thorough course in this subject; indeed, no medical school at the present day can afford to be without such a course of study if it hopes to rank with the leading institutions of the land, or aims to provide instruction of the highest and fullest type.

And now just a word or two regarding the character of a course in physiological chemistry. There may obviously be different views upon this subject. I can simply present my own. First, I believe that the student should be taught, in the laboratory of course, the general reactions and properties of the various albuminous or proteid bodies, studying likewise their more common decomposition products, their relationships and chemical constitution so far as known. Next in order come the various forms of epithelial and connective tissue, the student separating for himself and studying the various albuminoids which give character to the respective tissues, as the collagen of white fibrous tissue and the gelatin derived from it, the elastin of yellow elastic tissue, the so-called chondrin from cartilage, together with mucin and nucleo-albumin from the mucous tissues. Adipose tissue naturally comes next, and the several fatty acids are separated and studied, melting points determined, and the differences between the natural fats noted. This preliminary work, which involves much more chemistry than can be readily indicated by this short description, is followed by a study of the more important muscle tissue; the properties of muscle, plasma, and muscle-serum are noted and the various proteids and crystalline extractives characteristic of this tissue are prepared and examined. Myosin, the proteid of muscle clot, is especially studied and its resemblance to the related globulins of blood plasma noted.

Again, it must not be forgotten that in order to make such a course as I am outlining of the highest value, no opportunity should be lost to show the physiological bearing of all the results obtained; to try and instill into the mind of the student the idea that the facts of physiological chemistry have a wide application. Thus in the chemical study of muscle tissue, for example, many lectures and recitations may properly be interspersed; sections, for instance, from Foster's *Physiology*, making an admirable addition to the laboratory work, the object being to teach the student to make use of physiological chemistry as a means toward a broader and more accurate conception of physiological phenomena.

Muscle tissue is followed by a study of nerve tissue, the various bodies especially characteristic of this tissue, such as lecithin, myelin, cerebrin, protagon, and cholesterolin, being separated and their general properties and reactions ascertained. The chemical differences between the gray and white matter are also noted, the neuroglia, neurokeratin, and brain proteids are studied, while chemical and anatomical relationships are compared in this as in all other tissues examined.

The study of digestion is taken up next, the various secretions—salivary, gastric, pancreatic, and intestinal—being thoroughly examined. Artificial digestive juices are prepared and their action on the various classes of foodstuffs noted and compared, this serving likewise to illustrate the general action of enzymes or soluble ferments in distinction from the organized ferments. The many products of amylolytic and proteolytic digestion are prepared and separated, their chemical and physiological properties ascertained, and a thorough study made of both the chemical

and physiological side of digestion in its broadest sense, it being the writer's custom at this point to have the students study and recite, in connection with their laboratory work, nearly all of Book Second of Foster's *Physiology*, which treats especially of the tissues of chemical action with their respective mechanisms and of nutrition in general.

In a similar manner, the liver with its secretion, the bile, glycogen and glycogenesis, the spleen, blood, milk, and urine are all studied, and the proximate principles giving character to the several organs and secretions separated and examined. Further, the metabolic activity of the hepatic cells and likewise of the kidney cells is demonstrated by appropriate tests, such as the synthetical production of hippuric acid through the agency of the cells of the *tubuli uriniferi*. The chemical changes incidental to respiration are also experimentally studied, and the detection of blood stains by spectroscopic and other methods duly considered.

To the urine special attention is given, students being taught not only to make examinations of this important excretion, but likewise to determine quantitatively the urea, uric acid, phosphates, chlorine, sulphates, combined sulphuric acid, hippuric acid, creatinin, indican, sugar, albumin, and other abnormal constituents. Further, by daily quantitative examinations of the twenty-four-hours urine, opportunity is given to demonstrate many of the truths of nutrition or general metabolism, such as the influence of various forms of diet on the excretion of urea, uric acid, phosphoric acid, and combined sulphuric acid, the influence of drugs on proteid metabolism, etc.

This outlines very briefly the general character of a course in physiological chemistry such as I would see open to every student of medicine. To one interested in this phase of physiological work such a course of study would naturally serve as a preliminary to more advanced work, which might readily deal with many interesting problems bearing directly upon medicine and medical practice. There is, in fact, almost no limit to the many questions constantly arising that demand the aid of physiological chemistry for their solution.

A CLINICAL STUDY OF PERTUSSIS,

WITH SPECIAL REFERENCE TO THE HEART AND CIRCULATION.

By E. HELEN KNIGHT, M. D.

THE following notes were made on a series of forty cases of pertussis which were seen in a period extending over six months of the present year. The cases were first seen in the service of Dr. Koplik in the Good Samaritan Dispensary and were then visited at their homes, they reporting at intervals at the dispensary. Many of the cases did not come under observation until the spasmodic stage of the disease had set in. The more severe cases were visited once or twice a day while the severe symptoms continued. The milder cases were seen once a day or every other day. The ages of the children ranged from three weeks to ten years. In the study of the cases especial note was taken of the heart and circulation; temperature elevations—in absence of abnormal lung signs;

the condition of the urine; the frequency of the paroxysms and their severity; and effects of certain modes of treatment.

As to the heart and circulation, it is suggested by a number of observers that the heart is under a great strain during the paroxysms of coughing in pertussis, and that the strain is observed in the venous and arterial as well as in the capillary circulation. Also, some authors admit that it is but slowly that the heart regains itself after the paroxysm is over. Steffen (von Ziemssen, vol. vi, p. 696) remarks: "During the attack the action of the heart is essentially impeded and may momentarily cease." Also, "We must assume a transient dilatation of the heart which has an injurious effect upon its action." And again, "After the paroxysms the heart gradually regains itself and, by physical examination in the intervals, is found normal." Eichhorst states that "during the paroxysms the heart's action intermits and the pulse becomes weak." Osler remarks: "The heart stands the strain remarkably well. During the spasm the radial pulse is small, the right heart is engorged, and during and after the attack the cardiac action is very much disturbed."

We have, then, the statements that the heart does bear a strain in pertussis, it being granted by some observers that the organ only gradually recovers itself after the cessation of the spasm. In the study above referred to an effort was made to discover not only the nature of the strain during the paroxysms of pertussis, but also whether such strain persisted in the intervals of the paroxysms, and, if possible, the anatomical condition of the heart which was subjected to this strain.

In these cases the phenomena exhibited by inspection and palpation were that the action of the heart was in many cases irregular in rhythm and also in force during the spasms, and in many cases irregularity was present in the intervals and until the following spasm occurred. The length of time taken for the heart to regain itself varied from about ten seconds to several minutes. The action of

the heart was rapid in all cases, in some disproportionately to the respiration.

The data obtained by percussion and auscultation were more accurate. The method of examination by percussion was devised by Dr. Koplik from plates given by Walshe (*Diseases of the Heart*, p. 3) and by Symington (*Anatomy of the Child*, p. 64). It is as follows (see diagram): A line drawn from the point of apex beat through the junction of the third costosternal articulation on the right side (lower part) represents the median ventricular line. The highest point of the ventricle is the junction of the third rib (lower border) with the sternum on the right side. The radius of the ventricular base runs from the junction of the fourth rib (lower part) and sternum on left, upward, and strikes the middle or the upper part of the third rib. Dullness noted to left of mammary line; to right of midsternal line, in fourth space; and on left side on third, fourth, and fifth ribs.

TABLE A.

Case.	Age.	PAROXYSMS.		MEASUREMENTS IN CTM.	
		Intensity.	Frequency.	To right of mid-sternal line.	With mammary line.
1.	1 yr. and 4 mos.	Severe.	Frequent.	2½	In line.
3.	6 yrs.	Moderate.	Moderate.	1¾	"
8*.	3 yrs.	Moderate (heart case).	"	4	"
10.	10 yrs.	Severe.	"	3	"
11.	7 yrs.	"	Frequent.	2½	½ outside.
12†.	3 yrs.	Mild (heart case).	Few.	2½	½ inside.
13.	1 yr.	Severe.	Frequent.	1½	½ inside.
14.	3 yrs.	"	"	2½	In line.
15.	6 yrs.	"	"	2½	½ inside.
18.	4 yrs.	"	"	2	"
19.	6 yrs.	"	Moderate.	2½	In line.
21.	10 yrs.	"	Frequent.	3	"
29.	4 yrs.	"	Moderate.	2½	"
30.	4 yrs.	Moderate.	"	2½	½ inside.
33.	4 yrs.	Severe.	Frequent.	2½	In line.
40.	6 yrs.	"	"	2	½ inside.

* Case 8, when first seen, was characterized by a loud murmur of aortic insufficiency.

† Murmur of mitral insufficiency present in Case 12 when first seen.

The position of the apex beat in the child is so variously given by different authors that we but state here the position as it was found in these cases—viz.:

In the mammary line, nine cases; inside the mammary line, six cases; outside the mammary line, one case.

Steffen has given the figures for the measurement of the heart to the right of the midsternal line in a great variety of cases. He gives for the ages mentioned 0.11 centimetre less than our measurements show. In some cases of pertussis the heart is found by percussion tests to extend to the right of the midsternal line to an extent equal to the largest measurement normally, and in this series of cases they record the dullness from a centimetre and three quarters to three centimetres to the right of the midsternal line. Case No. 8, showing four centimetres to the right, is not mentioned here, for the reason given in the table. The percussion in these cases of pertussis can be said to be persistently large. It is, of course, difficult to fix a dilatation which passes the normal only by 0.11 centi-

metre, but if we find, in a large series of cases, a percussion area which equals the largest limit put down as normal by competent observers, or even surpasses this limit, we can justly think of overdistention or relaxation of the ventricle.

In thinking of the causes of possible dilatation of the right ventricle, we note here that Allbutt (*St. George's Hospital Reports*, 1870, p. 23), writing of the changes found in the hearts of laborers or soldiers who lifted heavy weights or who made forced marches while expansion of the chest was hampered by position or clothing, showed in many cases dilatation of the right ventricle, in a less number dilatation of the left, and in a still less number dilatation of both ventricles.

Black (*Lancet*, 1872, vol. ii, p. 253) states that mechanical influences, he considers, are largely responsible for diseases of the right heart, while those of the left heart more frequently arise from tissue inflammation. Again, that the former are passive and secondary while the latter are active and primary.

We have concluded that, if dilatation of the right ventricle can not be mapped out, we can conservatively assume from our studies a passive distention of this side of the heart in severe cases of strain in pertussis.

The facts obtained by auscultation were, in part, verifications of former statements. The rhythm of the heart was disturbed in twenty-five out of forty cases. In six cases this disturbance existed to a marked degree, the heart taking a considerable time in which to regain itself after cessation of spasm.

The spasm itself we find thus classically described by Niemeyer (vol. i, p. 95): "The coughing fit begins with a long-drawn, clear piping sound produced as the air is slowly drawn into the contracted glottis. Then follows a series of short, sharp, rapidly interrupted expiratory coughs, and this in turn is succeeded by the crowing, long-drawn inspiratory act."

The experiments of Müller and Valsalva show that in forced inspiration (Müller) there is the long-drawn inspiratory act with dilatation of the right heart, congestion of blood-vessels of lungs, with deprivation of blood from the left heart and systemic circulation, and decrease in the pulse tension; and then in forced expiration (Valsalva) the heart is compressed, the veins are congested, the blood is forced into the left ventricle, and then out of the thorax, causing emptying of heart and lungs with weakened heart sounds and reduction of the pulse. These experiments reveal the condition of the heart and circulation during or immediately after the paroxysm in pertussis.

In nine of the more severe cases of this series the heart sounds became changed as follows:

In one case the first sound at apex became roughened.

In one case the first sound at apex was accompanied by a slight murmur.

In one case the second sound became roughened at apex and base.

In six cases the second sound became accentuated—four over the pulmonic orifice, one over the aortic, and one over both orifices.

In two cases loud heart murmurs existed when the chil-

dren were first seen—one a murmur of aortic insufficiency, the other of mitral insufficiency. These are the cases (Nos. 8 and 12) given in the table as heart cases. It was not determined if the murmurs were old or new.

In regard to the question of heart murmurs in pertussis we quote from Osler: "It is difficult to determine if serious damage ever results. Possibly some of the cases of severe valvular disease in children, who have had neither rheumatism nor scarlet fever, may be attributed to the terrible heart strain during a prolonged attack of whooping-cough."

As to the causes of changes in the heart sounds and of the murmurs which arise, we merely question if they may be due to the violent alterations which take place in the heart's own blood supply, or from an impoverished condition of the blood generally (hæmic), or to some more purely mechanical causes to which the heart may be subjected, first during the acute dilatation and then during the acute compression in forced inspiration and forced expiration. The above factors may be active in causing valvular incompetency of a mechanical nature in the intervals of the paroxysms.

That the arterial pulse is disturbed is shown by irregularity, rapidity, dicrotism, and sustained tidal wave. The following table shows the pulsations persistently rapid and the respirations high:

TABLE B.

Case.	Pulse.	Respiration.	Case.	Pulse.	Respiration.
2	146	28	26	120	28
"	120	30	"	104	24
"	100	22	"	120	32
"	120	26	"	112	22
15	96	20	35	124	24
"	120	24	37	120	26
"	100	22	"	140	32
16	100	36	"	128	24
26	112	28	"	128	28
"	120	28	"	128	32
"	104	24			

The most marked features of disturbance are dicrotism and sustained tidal wave, these conditions showing, as is well known, abnormal distention and relaxation of the coats of the blood-vessels. These features are plainly shown in the accompanying sphygmographic tracings.

FIG. 1.—Normal trace: healthy child aged thirteen years: irregularity and slight dicrotism.

FIG. 2.—Pertussis, one hour after a paroxysm, showing sustained tidal wave and dicrotism.

FIG. 3.—Pertussis, same as above, five minutes after a paroxysm.

FIG. 4.—Pertussis, showing irregularity and dicrotism; female, aged ten years.

FIG. 5.—Pertussis, same subject as Fig. 4, showing irregularity and dicrotism; female, aged ten years.

FIG. 6.—Dicrotism of pertussis ten minutes after a paroxysm.

FIG. 7.—Dicrotism of mitral disease, mitral regurgitation.

FIG. 8.—Child aged ten years; had pertussis five years ago.

FIG. 9.—Same as Fig. 8.

In two cases where dicrotism existed there was a history of pertussis five years before. We call attention to the fact that slight dicrotism is present in the pulse of the normal child, which is also shown here.

The signs of capillary disturbance are well known—minute hæmorrhages, subcutaneous and into the mucous membranes. Signs of venous disturbance are the accepted ones of œdema of face and eyelids, engorgement of the large veins, cyanosis, dyspnoea upon slight exertion, languor, somnolence. Besides these we have the purely subjective symptom of complaint of the heart's action which occurred in three of the forty cases. In two cases the pain was spoken of as being very severe. The vaso-motor disturbance, as evinced by the flushings, was also marked in some cases. As signs of disturbance of the circulation caused by heart strain, we notice, then, particularly, large heart area to the right, slight changes in the heart sounds, rapid pulse, dicrotism, dyspnoea, languor, somnolence.

Temperature Elevations.—In fifteen per cent. of the cases it was above normal without abnormal lung signs; in one case as high as 101.2° axillary. Some mild cases and some severe ones were ushered in by fever; degree not known.

The percentage of lung complications in the forty cases was as follows: 47.5, slight bronchitis; 20, severe bronchitis; 17, broncho-pneumonia; 15, no abnormal lung signs.

Areas of emphysema were present in about twenty per cent. of the cases.

Condition of the Urine.—Steffen found that albumin may be contained in the urine in pertussis. Sugar has been found (Eichhorst, Osler). "Investigations as to blood are wanting" (Steffen). The urine was studied in twenty out of the forty cases—i. e., in those in which it was obtained without catheterization. Number of examinations made, 86. Reaction acid in all but two examinations. Specific gravity, 1.020, average; from 1.025 to 1.030 during height of paroxysms in several cases, though in some cases even at this period the record shows but 1.004 to 1.006 even where albumin was present.

The presence of albumin in a large proportion of the cases (sixty-six out of eighty-six examinations), and of hyaline and epithelial casts in a small proportion of the cases (two out of eighty-six examinations), may be due to conditions first suggested by Rosenstein. When, either through insufficient compensation or lack of the same, exhaustion of innervation, fatty degeneration of the heart muscle, or lack of correlation between dilatation and hypertrophy, there results lowered arterial tension and, after a time, surcharge and increased tension of the venous system (as a result of the close relation between pressure conditions and rapidity of circulation on the one hand, and the secretory functions of the kidneys on the other hand), the kidneys, in the lowered arterial tension, excrete less urine than normal, the specific gravity is increased, albumin and fibrin cylinders make their appearance.

Albumin, a few blood-cells, and a few hyaline cylinders were present in one case, which had all the symptoms of heart strain, and in which the albumin and blood persisted for a long time into convalescence. Passive hyperæmia of the kidney in this case could be justly assumed. The albumin and casts and also the blood-cells suggest possible effects of an infectious disease, or the blood-cells may have originated from muscular strain. In cases of pertussis, where there are signs of heart strain without fever, the presence of albumin in the urine must weigh in favor of circulatory disturbance in the kidney, as in other parts of the body, in

addition to the possible effects of an infectious toxine. The presence of leucocytes is not considered especially worthy of comment. The sugar and acetone may be due to imperfect digestion, and are but mentioned, as their presence has no direct bearing upon the subject of the paper.

Effects of Certain Modes of Treatment.—In all cases antipyrine was administered from the time the children were first seen. In all cases where heart strain was manifest during the intervals (as evidenced by markedly rapid or irregular or dicrotic pulse, by cyanosis, great languor or malaise, by dyspnea or complaint of heart) digitalis was added to the antipyrine. In all cases where pertussis existed independent of severe broncho-pneumonia the above treatment proved effectual. In three cases, where severe broncho-pneumonia existed and cyanosis was extreme, exhibition of digitalis was followed in twenty-four hours by reduction of unfavorable symptoms. In ten cases, where marked oedema of the face and cyanosis existed without broncho-pneumonia, digitalis markedly relieved the patients. Antipyrine was given in doses of one grain for every year; maximum dose, five grains. Tincture of digitalis, one minim for every year; maximum dose, four minims. The effects of treatment will be best illustrated by citing a few of the cases:

CASE VII.—Celia B., aged one year; coughing two weeks, about fifty times in twenty-four hours; whoops hard; bronchitis present. Antipyrine. The patient failed to report at dispensary; brought ten days later. At this time cyanosis marked, pulse poor, paroxysms severe. Antipyrine and digitalis, with great relief in forty-eight hours.

CASE VIII.—Hyman B., aged three years; coughing three months; expression of intense distress; loud basic murmur of aortic insufficiency, which became much less marked after administration of digitalis, and within one week improvement marked. When seen six weeks afterward, murmur was scarcely audible. No abnormal lung signs.

CASE X.—Emma W., aged ten years; coughing three weeks; paroxysms severe, about twelve in twenty-four hours; lies down most of the time; oedema of face and eyelids. Antipyrine. Improvement within five days. No abnormal lung signs.

CASE XI.—Louis L., aged seven years; coughing three weeks; the last week cough very hard; languor and somnolence marked; oedema, cyanosis, and dyspnea; albuminuria and casts. Thirteen spasms in twenty-four hours. No abnormal lung signs. Antipyrine and digitalis. In sixteen days, spasms reduced to five in twenty-four hours. When examined two months later, although albumin was present, casts had disappeared from urine.

CASE XXXIII.—Lena W., aged four years; has been coughing two weeks, whooping two days; eats nothing; languid and somnolent; cyanosis; oedema of face and eyelids; broncho-pneumonia of right side posteriorly; pulse rapid and markedly irregular. Improved upon antipyrine and digitalis, but not until the latter was given in maximum dose for age.

I desire to express my obligations to Dr. Henry Koplik, in whose service in the Good Samaritan Dispensary these studies were made, and who kindly controlled the progress of the work.

321 EAST TENTH STREET.

A HAND OPHTHALMOMETER AND RETINOSCOPE COMBINED.

By JOHN HERBERT CLAIBORNE, JR., M.D.,
ADJUNCT PROFESSOR OF OPHTHALMOLOGY, NEW YORK POLYCLINIC.

The instrument of which the accompanying cut is a representation is a modification of Placido's disc for the recognition of astigmatism.

Placido's disc is nothing more nor less than a circular board upon which black and white circles alternate. It is perforated centrally by an aperture smaller than the one in the cut herewith shown, but quite large enough for seeing. The cut shows the alternate black and white circles, a large central aperture with numerous white lines traversing the diameter of the circle. On the back of the disc a revolving ratchet is attached in such a way that either a convex lens or a retinoscopic concave mirror may be thrown over the aperture. The cut shows the lens and the mirror detached from the disc. In the *New York Medical Journal* of June 25 and July 2, 1892, in a paper entitled *The Axis of Astigmatic Glasses*, I propounded the propositions that the axis of astigmatism does not occur at haphazard; that there are axes of preference both in hyperopic and myopic astigmatism and in their combinations; that the positions of preference in hyperopic astigmatism are five—namely, 90° , 105° , 135° , 75° , 45° ; that the quarter of the circle from 45° to 135° is the "realm of hyperopic astigmatism"; that the positions of preference in myopic astigmatism are three—namely, 0° , 15° , 165° ; that the third of the quarter of the circle from 15° to 165° is the realm of myopic astigmatism.

It will be seen that the diametric lines shown upon the disc correspond to these axes. The figures are reversed in order that they may appear natural when reflected from the cornea.

The lens behind the disc face may be of any strength desired; it can be removed and replaced. For my part, I find a + 10 D. most satisfactory. This lens gives a fair distance at which one may examine the reflex on the cornea without coming too near the patient. At the same time the reflection is sufficiently large to enable one to see the figures fairly well. The inspection is rendered far more satisfactory by the use of cocaine instilled into the observed eye, since by the use of this drug the palpebral slit is considerably widened. Ordinary daylight may be used, and of this kind of light the reflection from a white cloud is preferable. The gas jet, however, is satisfactory, though the light should be rendered brighter than usual through oxygen mixed with it or through a "Welsback" burner, which renders the light much more intense and white.

I have placed a concave mirror of nine inches focal distance on the other end of the ratchet arm, since the concave mirror which is found on the ophthalmoscope is the one ordinarily used in retinoscopy. It will be seen, therefore, that the instrument is intended as a combination of a portable ophthalmometer and a retinoscope. It is a well-known fact that the much-lauded ophthalmometer of Javal and Schiötz, while it gives the axis of astigmatism fairly accurately, gives no information as regards the character of the astig-

matism. The intention of the double combination in this instrument becomes immediately evident. The axis of the astigmatism having been indicated by the reflection on the cornea, its character is declared by the retinoscopic mirror. Artificial illumination is necessary for the use of the retinoscope; hence this form of illumination will enable one to get the results of examination with this instrument in the shortest time and with the least trouble. Of course, the reflection gives no definite information in regard to the amount of astigmatism, but the retinoscope gives a fairly approximate estimate. Any instrument which measures only

the corneal astigmatism must needs be more or less incorrect. This, too, sets limitations to the usefulness of the ophthalmometer of Javal and Schiötz.

The patient should look directly into the central aperture. If the vertical lines

appear shorter than the horizontal, or the horizontal appear longer than the vertical—i. e., are elongated—there is the so-called astigmatism *with the rule*, for three conditions are possible: First, there may be simple myopic astigmatism, since in this condition the vertical meridian is more sharply curved than the horizontal, and the

image reflected from it is smaller; secondly, there may be simple hyperopic astigmatism, since in this condition the horizontal meridian is less sharply curved than the vertical, and the image from it is larger; thirdly, there may be mixed astigmatism, since in this condition there is a sharper curve in the vertical meridian than in the horizontal.

If, then, the horizontal diameter appears longer than the vertical—i. e., if the reflex on the cornea appears elongated horizontally—there is astigmatism *with the rule*, and the three possibilities are simple hyperopic, simple myopic, and mixed astigmatism.

A turn of the retinoscopic mirror will cause one of these three to declare itself. The same picture is shown by compound hyperopic and compound myopic astigmatism, but so far as the astigmatism is concerned these conditions are the same as simple hyperopic and simple myopic astigmatism. If the vertical diameter appears longer than the horizontal—i. e., if the reflex on the cornea be elongated vertically—there is astigmatism *against the rule*, and one of the possibilities mentioned above exists.

Now, when the axis of astigmatism is neither vertical

nor horizontal some difficulty arises. It is difficult to place the axis at 75° or 105° , 15° or 165° , but at least this much can be seen: the axis is just off the vertical or horizontal. If it be further off the vertical than 75° or 105° , or further off the horizontal than 15° or 165° , it is in the great majority of cases 45° or 135° , and when it is at this angle it is fairly clearly shown.

If the lesser diameter be found at 105° —which is the same thing as the greater diameter or the elongation being found at 15° —there is still astigmatism *with the rule*, and there is simple hyperopic astigmatism (axis 105°), or simple myopic astigmatism (axis 15°), or mixed astigmatism with the axes in their proper realms. If the lesser diameter be found at 75° —which is the same thing as the greater diameter on elongation being found at 165° —there is still astigmatism *with the rule*, and one of the three conditions above mentioned exists with the axes in their proper realms.

Now, simple hyperopic astigmatism hardly ever occupies the axis 15° or 165° , and simple myopic astigmatism hardly ever occupies the axis 75° or 165° , so that I do not deem it necessary to treat these conditions theoretically.

In mixed astigmatism the axis 45° or 135° , which properly belongs to the realm of hyperopic astigmatism, not infrequently is taken by the myopic axis. Let us suppose a case in which the elongation of the reflex is in the axis 45° .

It may be safely said that the possible conditions are simple hyperopic or mixed astigmatism, for simple myopic astigmatism rarely occupies this angle. Suppose it be a case of simple hyperopic astigmatism; the axis of the convex cylinder would be, of course, 135° , since the diameter of 45° would be less curved than that of 135° .

If it were a case of mixed astigmatism, the axis of the convex cylinder would be 135° and that of the concave 45° for obvious reasons. In taking these observations it is better for the patient to look slightly outward in order to avoid the shadow of the brow and nose obscuring the reflex on the inner side of the cornea.

The instrument is made by Meyrowitz.

10 EAST TWENTY-EIGHTH STREET.

The Southern Surgical and Gynecological Association will hold its next meeting in New Orleans on the 14th, 15th, and 16th of November.

The Death of Dr. Henry B. Millard is announced as having taken place in Paris on Tuesday of last week, as the result of typhoid fever, in the sixtieth year of his age. The deceased was a graduate of the Medical Department of the University of the City of New York, of the class of 1858. Early in his professional life he became a homœopathist, but several years ago he returned to the ranks of the regular profession, and after that he entered upon a course of investigation in the pathology of the kidney, and especially in uranalysis, that made his writings on those subjects rank among the most important. He was in the habit of spending his summers in Paris, and he was much esteemed by the physicians of that city. He was a member of the *Société anatomique* and a foreign corresponding member of the *Académie de médecine*. He was also a member of the New York Academy of Medicine and of the Medical Society of the County of New York.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & CO.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, SEPTEMBER 30, 1893.

THE PHYSICIAN AND THE REPORTER.

THERE are many worse things in this world than newspaper reporters and newspaper correspondents. They do good and disseminate much of commercial, religious, literary, and scientific matter, as well as other things. By their labors they refresh many souls—souls that yearn for social scandal; that lust after that clairvoyance which enables its fortunate possessor to select the fleetest among the steeds that are to fly in competition around the orb'd track and to win wealth thereby; that sigh for the flesh-pots of the Stock Exchange; that bask in the ruddy light shed by a realistic description of some "tragedy in real life." But we regret to state that the soul medical rarely finds comfort in their efforts in its behalf, for these are too often either condemnatory of it or uninteresting to it. They have a gentle custom of gloating over the failures of medical science and of jeering at its votaries. They disinter ancient sarcasms at the expense of physicians, adding to the scoffs doubtless cast at Hippocrates by the gamins of ancient Greece—similar to, if not so cutting as, those which, not entirely disconnected with alopecia and she-bears, enriched the history of Israelitish prophets—adding to these the modern mockings of this age, and cast all at the shrinking medical man at regular intervals. This is a trifling sin. But they do not stop at this. They mangle the doctor's technical terms. They interview him and then misquote him. They laud his profession to the skies as scientists in one paragraph, and in another disqualify it collectively and individually from the simple and menial task of carrying abdominal viscera to a bear. They insult his instruments by calling them "cruel-looking," "keen and glittering," etc., and usually call him "handsome" when he knows better, and put upon him personal slights without number. The physician becomes accustomed to such trifles and expects them, but when it comes to the reporting of rare and interesting cases by men who have no idea of their importance to the scientific observer he must utter a protest. It is a small thing for a newspaper man to sit down and write up the history of the particular *homo Natura* which he has recently discovered, embodying very important conditions to the scientist, and condense it into one small paragraph, but it is worse than death to the physician to read it, mainly because of the crude way in which it is treated, for the rare case is as the apple of his eye to the physician. He loves to observe it and to prattle about it; to discuss it in all its bearings on the past, the present, and the future; to write it up, dressing it in voluminous robes of rhetoric, and to put foot-notes on it. But in spite of this he sees his cherished prerogative usurped by a paragrapher who knows not the

A B C of the science with which he tampers, and is careless of the heart on which he tramples. No, he goes on with his brutal brevity in the matter pertaining to medical science, and then devotes three columns with illustrations to the minute description of some infant's swaddling clothes, making even them of uncut cloth! This may call down upon him the contumely of his brethren attached to other newspapers, and may be thereby a cause of his advancement in his station on the staff of his own paper. He may even be detailed to the noble duty of disguising himself as a polyglot *valet de chambre* to some visiting noble and then allowed to publish facts or fancies in regard to the grandee's private life. But he passes over in a few curt lines the negro of Tennessee who attempted to raise tropical fruits by swallowing a lemon seed, which presently sprouted and which would undoubtedly have flourished like the green bay tree had but the horticulturist survived. He does not notice that the hardy seed failed to follow the beaten track pursued by similar pilgrims through the gastro-intestinal canal to the Mecca of its kind, the vermiform appendix, and he shatters all precedent by making the gastric garden he describes a botanical rather than a zoological one—an action which must have caused much commotion among the bones of dead and buried reporters. Now, if he had made his negro the victim of misplaced confidence in a swallowed parrot's egg, both the ensuing parrot and the trusting colored man would have lived and warbled duets together, while Polly's demands for watermelon would have given its foster father an excuse for raids on the neighboring patches. Again, he tells us in three or four lines the history of the case of a gentleman of Georgia who, some twenty-five years since, during the strained relations which existed between the Northern and Southern States, while in the middle of a discussion with some gentlemen of views opposed to his own, was temporarily obliged to discontinue the debate on account of the extremely rapid advancement of an argument in the shape of a Minié ball, which not only reached the seat of his argumentative powers, causing him much discomfort, but has also remained with him to this day, as if ready to meet any new proposition which he might advance. We are informed that this leaden syllogism "shifts around" within the patient's cranium "in the front of the head; at another time in the back." At times it gives Mr. — "much uneasiness while at work in the field by its shifting about and the rattling noise it makes in the head"—probably to the great delight of the baby.

And this is all that a newspaper man has to say regarding a case of this description! There is neither science, imagination, poetry, nor logical reason in him. He cares not for the delight of investigation of the general architecture of the Georgia skull which can accommodate a brain and a perambulatory bullet at the same time, and he does not stop and think of the fidelity of that same wanderer. That Minié ball was an argumentative one, and was put in its present location for a purpose. It is searching for its enemy, and the eye grows moist at the thought of its weary search for an idea. It "shifts around," rushing through the chambers of memory and slamming the doors, all in vain. Then it waits in the back of the head until

ashamed of its sloth, and "shifts" to the front door, looking up and down the avenues of thought until it makes a mad dash over the rattling paving stones at the sight of a brain cell which looks as if it was evolving a thought pertinent to the old discussion, only to make the discovery that it has again been foiled, and that no idea is present.

One more instance of the reporter's depravity is his account of the case of a small boy who, after suffering for several years under the curse of "some baffling eye disease," suddenly recovered his sight with alarming additions. His recovered vision was microscopic and he saw plant lice as large as rabbits frisking over the begonias in the back yard, while mosquitoes with "bills as large as ax-handles" fluttered about him with the evident design of inserting the same into his most cherished anatomical regions, to say nothing of animals and birds of fantastic appearance in the distance. The boy fled with energy and in terror, until he reached the family well and attempted to overcome his agitation by taking a draught of pure cold water. Water has not passed his lips since, for, on raising the moss-covered bucket to his lips, he beheld its contents and saw myriads of uncouth and ghastly things tearing and rending one another, staring at him with searching looks, and reaching out endosmotic processes, swarming in the water he was about to swallow. This was too much, and the boy again fled. There are a few unimportant details as to the opinion of local physicians about the case, such as "the structures of the eyes having undergone complete change," but nothing is reported as to the probable result of this remarkable phenomenon. Though he can be induced at times to drink water, it is only under the guise of a "cuppotea"—he will not touch it in its natural state.

Now consider the fate of that boy. He will become the village sot, after refusing to be an angel on account of some weird thing with wings which he will see flying high up in the sky and which may appear to his untutored mind to be a seraph, and then his case will be sad. His first attack of *mania a potu* will surpass in scope the worst case on record and is terrible to contemplate. Think upon what he is accustomed to see while in a condition of sobriety, and then ponder on what it may become when hallucinatory influences are at work! Nile-green tigers, Scotch-plaid simians, ultramarine rats, and all of the common every-day results of the maddening cup will march before him led in chains of streptococci by ravenous-looking and polychromatic animalcules. He will see the germs of all diseases descending upon him, and yet can not cool his parched mouth with a drop of water. After several attacks of this kind, if he should survive, there may be a hope for him. He must be made to drink only water warm from the still, and become a detective—not of the kind which goeth forth to see whom it may devour, but a bacteriological detective. His marvelous vision will serve him well when aided with a microscope, and he will be able to trace the development of every microbe from spore to ptomaine.

But even this plan offers but little encouragement. Who can say that when he is engaged in observing the development

of a colony of some new microbe which he has discovered there may not saunter into the field of his microscope some germ which he recognizes, but which he fears to be of a variety that he has only seen during some one of his lapses into the realm of fantasy? His only recourse is to immediately relapse, and when he finally attains to the desired state, he may find his new friend absent, but so many of his old, tried companions present that he can not make the observation which he had proposed to make. In his despair he will continue his evil courses until he makes so many new microscopical friends that his labors will only retard instead of advancing science.

The foregoing are but three out of the many instances where the newspaper man has almost daily maddened the physician—maddened him in every mood and tense. There seems to be little or no hope of abating this evil, for the reporter is an animal of wide range, and, even if the heart of one is touched, there are hundreds to take the place of the one convert. We can only lay the facts before our readers, and hope for some better time when Nature shall be more consistent and reporters shall have enough to report without invading the physician's domain.

MINOR PARAGRAPHS.

THE LARGEST PHARMACY IN THE WORLD.

ACCORDING to the *Chemist and Druggist*, July 29th, the pharmacy of Karl J. Ferrein, of Moscow, is the largest in the world, and puts up daily more prescriptions than any other. As many as twelve hundred prescriptions are put up in a day. The dispensing is done in a glass-domed room where twenty-four or more apothecaries are employed, and a clerical and apprentice force nearly as numerous gives a portion of its time to the reception, entering, and delivery of the goods ordered and prepared. If poisonous ingredients enter into the composition of a medicine to be prepared, the checking of weights is done by a weigher specially appointed for that purpose. The *coactorium* has its walls and floor and fittings, as far as possible, made of white marble, and every attention is paid to keeping it scrupulously clean. The lighting is done by electricity. In all, two hundred and ninety-three men and boys find employment in the retail and wholesale departments of the establishment. The average number of prescriptions is not far from three hundred thousand annually, and the average amount of money received for their dispensing is three hundred and sixty thousand roubles. It is alleged by the *Pharmaceutische Post* that this gigantic business is founded on a reputation earned by Mr. Ferrein for the purity of his drugs and for absolute accuracy in dispensing. The founder died in 1887, but his two sons perpetuate their father's name and methods of business.

JOURNALISTIC APPRECIATION OF MEDICAL MEN.

A PLEASING offset to the abusive newspaper article that we republished last week is the following, written apropos of the late Dr. Vought, which appeared in the editorial columns of the *Sun* on Thursday of this week:

"There are always risks for doctors in attendance upon patients suffering from contagious or infectious maladies. Yet they are always ready to brave the danger, without flinching, in the interest of humanity. Honor to our noble army of doctors!

"Hundreds of them volunteered for service here last autumn when the city was threatened with cholera. We do not know how many of them have sent word to Surgeon-General Wyman that they stand ready to go to Brunswick or to any other part of the South in which the yellow fever may break out. Whatever be the risks from any disease, the medical faculty is ever willing to confront them. Long live the doctors! We have sent American doctors to the cholera-infected ports of Europe, and several of them have done splendid work there this year. If a hundred of them had been needed, we have no doubt that a thousand of them would have offered their services. Heroes are the doctors. They will enter a pest house without shrinking, attend to every case in it, and do all that can be done to relieve the sufferers. Blessed be the doctors! They are men of science, men of skill, men of earnest purpose, men of sympathetic disposition. They are devoted to their duties. Dr. Walter Vought, who died of typhoid fever last Sunday in the New York Hospital, of which he was house physician, was a man of talent, and still in his early prime. He took charge of the quarantine station at Fire Island last year during the 'cholera scare'; he had rendered service in the Vanderbilt Clinic; he died in a hospital. Though he had but just turned thirty years of age, he was the author of works upon malarial fevers, the cholera, and other diseases; he had already won a name in the profession. We knew him personally, and we can testify that he was a high-minded gentleman.

"There's rosemary, that's for remembrance; . . .
and there is pansies, that's for thoughts."

THE PALMO-PLANTAR SIGN OF TYPHOID FEVER.

DR. FILIPOVITCH, of Odessa, thinks he has discovered a diagnostic sign of typhoid fever that may prove serviceable in cases where at first the usual pathognomonic symptoms are wanting. It is a peculiar callous look and an orange-yellow or saffron-yellow hue of all the prominent parts of the palms of the hands and the soles of the feet—parts which, as is well known, are more or less rosy in health and become bluish in cases of cyanosis. The phenomenon is explained by the enfeebled action of the heart, a diminished amount of blood in the capillaries, and the dryness of the skin. He has observed it in every case seen by him during the last two great epidemics of typhoid fever in Odessa, and his observation is confirmed by another Russian physician, Dr. Skibnevsky. The sign disappears as soon as convalescence begins.

Dr. Filipovitch's article appeared in the *Revue médicale* for August 20th, and an abstract of it is given in *Lyon médical* for September 10th.

A DEATH BY CHLOROFORM.

At the Methodist Episcopal Hospital of Brooklyn a death from chloroform recently occurred. The patient was under treatment for dislocation of the humerus. A very small quantity of the anæsthetic had been administered when fatal syncope set in.

THE INDIAN MEDICO-CHIRURGICAL REVIEW.

A NEW journal thus entitled, published in Bombay, has appeared as an organ of the native surgeons and physicians of western and northern India. It is published monthly under the editorship of N. H. Choksy, M. D.

ITEMS, ETC.

The Army Medical School.—By direction of the Secretary of War, upon the recommendation of the Surgeon General of

the Army, the faculty of the Army Medical School, established by General Orders No. 51, June 24, 1893, from this office, and regulations for the government of the school are announced as follows: Colonel Charles H. Alden, assistant surgeon general, U. S. Army, president of the faculty and lecturer on the duties of medical officers; Lieutenant-Colonel William H. Forwood, deputy surgeon general, U. S. Army, professor of military surgery; Major John S. Billings, surgeon, U. S. Army, professor of military hygiene; Major Charles Smart, surgeon, U. S. Army, professor of military medicine and director of the chemical laboratory; Captain Walter Reed, assistant surgeon, U. S. Army, professor of clinical and sanitary microscopy and director of the pathological laboratory; Captain Julian M. Cabell, assistant surgeon, U. S. Army, assistant to the professor of military surgery and instructor in Hospital Corps drill. "The course of instruction will be for four months, and will be given annually at the Army Medical Museum, in Washington city, commencing on the first day of November." It will include lectures on and practical instruction in—1. The duties of medical officers in war and peace. 2. Military surgery, the care of the wounded in time of war, and hospital administration. 3. Military hygiene. 4. Military medicine. 5. Microscopy, sanitary and clinical; pathological histology, bacteriology, and urinalogy. 6. Hospital Corps drill, and first aid to the wounded. By permission of the Surgeon General, medical officers of the army who desire to avail themselves of the course of instruction, and who are stationed in or near the city of Washington, or who have a leave of absence which enables them to attend the course, may be admitted as pupils under the same regulations as apply to recently "approved candidates for admission to the medical corps of the army." At the termination of the course of instruction the "approved candidates for admission to the medical corps of the army" will be examined by the several professors, and their relative proficiency in each branch will be reported by the president of the faculty to the Secretary of War through the Surgeon General of the army. The regulations are as follows: 1. The president of the faculty will be responsible for the discipline of the school. 2. The junior professor will act as secretary and will be responsible for all property pertaining to the school. 3. A faculty meeting will be held in the office of the secretary on the first Monday of each month from October to March, inclusive, and whenever called by the president of the faculty or the Surgeon General of the army. 4. Resolutions adopted by the faculty relating to the course of instruction, the purchase of books and instruments, etc., will be submitted to the Surgeon General of the army for his approval. 5. The president of the faculty will submit to the Surgeon General of the army, on or before the 1st day of April of each year, a detailed report of the condition of the Army Medical School, including an account of the instruction given and the proficiency of the several pupils as shown by an examination made by each professor at the termination of his course. 6. The hours of instruction will be from 9 to 12 A. M., and from 1 to 4 P. M., daily, from November 1st to February 28th, inclusive, with the exception of Saturdays, Sundays, legal holidays, and the week commencing December 25th. 7. Pupils will be required to be present during the hours designated unless specially excused by the president of the faculty or by orders from the War Department. 8. When necessarily absent on account of sickness or other emergency, pupils will, as soon as practicable, send a written statement to the secretary of the faculty explaining the reason for such absence. 9. The laboratories and library of the Army Medical School will be open for the use of pupils during the hours of instruction designated. 10. Pupils will be held strictly accountable for all instruments and apparatus issued to them

for their personal use during the course of instruction, and for any loss or injury to books or apparatus belonging to the Army Medical School, when such loss or injury is due to carelessness or neglect. 11. Pupils in the Army Medical School, during the hours of instruction, will wear the undress uniform of the grade to which they belong, except when engaged in laboratory work, when a black cambric laboratory gown may be worn.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 26, 1893:

DISEASES.	Week ending Sept. 19.		Week ending Sept. 26.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	0	0
Typhoid fever.....	33	7	26	8
Scarlet fever.....	44	4	41	5
Cerebro-spinal meningitis.....	1	0	1	1
Measles.....	41	5	56	4
Diphtheria.....	99	31	87	31
Small-pox.....	18	3	38	3

The New York State Association of Railway Surgeons.—The third annual meeting will be held under the presidency of Dr. George Chaffee, of Brooklyn, at the New York Academy of Medicine on November 15th. A cordial invitation is extended to the profession.

Professor Helmholtz has been invited to address the students of the College of Physicians and Surgeons (Medical Department of Columbia College) on Tuesday, October 3d, in the upper lecture-room. Members of the medical profession are cordially invited to be present.

Change of Address.—Dr. Charles H. May, to No. 692 Madison Avenue.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 17 to September 23, 1893:*

KIEFFER, CHARLES F., First Lieutenant and Assistant Surgeon, is relieved from further duty at Fort Meade, South Dakota, and from temporary duty at Fort Yellowstone, Wyoming, and will report to the commanding officer at Fort Assiniboine, Montana, for duty.

LEWIS, WILLIAM F., First Lieutenant and Assistant Surgeon, will, upon being relieved from duty at Fort Assiniboine, Montana, by Lieutenant Kieffer, report to the commanding officer, Fort Apache, Arizona, for duty.

BROOKE, BENJAMIN, First Lieutenant and Assistant Surgeon, will proceed at once from Fort Leavenworth, Kansas, to Fort Brady, Michigan, for temporary duty during the absence on leave of Assistant Surgeon Paul Clendenin.

CLENDENIN, PAUL, Captain and Assistant Surgeon, is granted leave of absence for one month, to take effect upon the arrival of Assistant Surgeon Benjamin Brooke.

PRICE, CURTIS E., Captain and Assistant Surgeon, is relieved from duty at Fort Wadsworth, New York, and ordered to report to the commanding officer, Fort Porter, New York, for temporary duty at that post.

SHANNON, WILLIAM C., Captain and Assistant Surgeon, is relieved from duty in the office of the Surgeon General of the Army, and as assistant to the attending surgeon in Washington, and will proceed to New York city and report in person to the commanding general, Department of the East, for duty as attending surgeon and examiner of recruits in

that city, relieving EDIE, GUY L., Captain and Assistant Surgeon.

HARRIS, H. S. T., Captain and Assistant Surgeon, is relieved from duty at Fort Keogh, Montana, and assigned to duty at Fort Preble, Maine.

WOOD, M. W., Captain and Assistant Surgeon, is relieved from duty at Fort Preble, Maine, and assigned to duty in Boston, Mass., as attending surgeon and examiner of recruits.

IVES, FRANCIS J., Captain and Assistant Surgeon, is ordered to proceed from Fort Sheridan, Illinois, to Chicago, Ill., and report to LA GARDE, LOUIS A., Captain and Assistant Surgeon, in charge of the medical section of the War Department Exhibit, World's Columbian Exposition, for temporary duty.

EDIE, GUY L., Captain and Assistant Surgeon, upon being relieved from duty in New York city, by SHANNON, WILLIAM C., Captain and Assistant Surgeon, will proceed to Washington, D. C., and report in person to the attending surgeon for duty in his office.

SPENCER, WILLIAM G., Captain and Assistant Surgeon, is granted six months' extension to sick leave of absence granted in Special Orders No. 108, A. G. O., May 13, 1893.

BRECHEMIN, LOUIS, Captain and Assistant Surgeon, is granted twenty-three days' leave, to take effect about September 17, 1893.

McLEDDERY, HENRY, Major and Surgeon, is granted leave of absence for one month, to take effect about October 1, 1893.

Marine-Hospital Service.—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Six Weeks ending September 16, 1893:*

MURRAY, R. D., Surgeon. To proceed to Pensacola, Fla., for temporary duty. August 10, 1893. To rejoin station. August 18, 1893. To proceed to Brunswick, Ga., for temporary duty. September 14, 1893.

BAILHACHE, P. H., Surgeon. To assume charge of inspection of immigrants. August 14, 1893. Detailed as chairman of board for physical examination of keepers of Life-Saving Stations. August 18, 1893. Relieved from duty as inspector of immigrants. August 22, 1893. Detailed as chairman of board for physical examination of officers of the Revenue-Marine Service. September 12, 1893.

PURVIANCE, GEORGE, Surgeon. To report at bureau for temporary duty. August 6 and 10, 1893. Detailed as chairman of board for physical examination of Surgeon John Vansant. August 28, 1893.

VANSANT, JOHN, Surgeon. Ordered before board for physical examination. August 31, 1893.

HUTTON, W. H. H., Surgeon. To report at Brunswick, Ga. August 10, 1893. To proceed to Cape Charles Quarantine as inspector. August 12, 1893. To proceed to Brunswick, Ga., for temporary duty. August 12, 1893. To rejoin station, Detroit, Mich. September 10, 1893.

HAMILTON, JOHN B., Surgeon. Granted leave of absence for four days. August 16, 1893. Granted leave of absence for ten days. August 29, 1893.

SAWTELLE, H. W., Surgeon. Detailed as member of board for physical examination, Life-Saving Station. August 18, 1893. Detailed as member of board for physical examination of Passed Assistant Surgeon H. T. Goodwin. August 22, 1893. Detailed as member of board for physical examination of officers of the Revenue-Marine Service. September 12, 1893.

AUSTEN, H. W., Surgeon. Detailed as recorder of board for physical examination of Surgeon John Vansant. August

28, 1893. To represent the service at meeting of the Pan-American Medical Congress. September 5, 1893.

GASSAWAY, J. M., Surgeon. To inspect local quarantine at Pascagoula, Miss. August 23, 1893.

MEAD, F. W., Surgeon. To proceed to Chicago, Ill., for temporary duty. August 9, 1893.

CARTER, H. R., Surgeon. To proceed to Fernandina, Fla., to inspect quarantine and return to bureau. August 7, 1893. To proceed to Pensacola, Fla. August 10, 1893. To proceed to Brunswick, Ga., for temporary duty. August 12, 1893. To report at bureau. August 31, 1893. To represent the service at the Pan-American Medical Congress. September 5, 1893. To proceed to Philadelphia, Pa., and Reedy Island Quarantine. September 9, 1893. To proceed to Cape Charles Quarantine and assume command. September 11, 1893. To report at bureau for temporary duty. September 13, 1893.

WHEELER, W. A., Surgeon. Detailed for duty at Camp Low. August 14, 1893. To rejoin station. August 22, 1893. Detailed as recorder of board for physical examination of Passed Assistant Surgeon H. T. Goodwin. August 22, 1893.

CARMICHAEL, D. A., Passed Assistant Surgeon. Granted leave of absence for thirty days. August 16, 1893.

PECKHAM, C. T., Passed Assistant Surgeon. Granted leave of absence for twenty days. August 10, 1893.

GLENNAN, A. H., Passed Assistant Surgeon. To proceed to Reedy Island Quarantine for temporary duty. August 30, 1893.

MAGRUDER, G. M., Passed Assistant Surgeon. To proceed to Pensacola, Fla., as inspector. August 10, 1893. To proceed to Brunswick, Ga., for temporary duty. August 23, 1893. To proceed to Beaufort, S. C., as inspector. September 9, 1893.

KINYOUN, J. J., Passed Assistant Surgeon. Detailed as inspector at New York Quarantine. August 12, 1893. Detailed as member of board for physical examination of Passed Assistant Surgeon H. T. Goodwin. August 26, 1893.

GOODWIN, H. T., Passed Assistant Surgeon. Granted leave of absence for thirty days. August 10, 1893. To proceed to Louisville, Ky., for duty. August 15, 1893. Ordered to appear for examination as to physical condition. August 22, 1893.

VAUGHAN, G. T., Passed Assistant Surgeon. To represent the service at the meeting of Pan-American Medical Congress. September 5, 1893.

GEDDINGS, H. D., Passed Assistant Surgeon. To report at bureau for temporary duty. September 13, 1893. To proceed to Brunswick, Ga., for temporary duty as inspector. September 15, 1893.

COPER, L. E., Assistant Surgeon. To proceed to Savannah, Ga., for duty. August 25, 1893.

DECKER, C. E., Assistant Surgeon. To proceed to San Francisco Quarantine for temporary duty. September 3, 1893.

NYDEGGER, J. A., Assistant Surgeon. To proceed to Jersey City, N. J., for temporary duty. September 2, 1893. To rejoin station. September 9, 1893.

OAKLEY, J. H., Assistant Surgeon. To proceed to Quebec, Canada, for duty. August 26, 1893.

NORMAN, SEATON, Assistant Surgeon. To proceed to New York, for temporary duty. August 18, 1893. To rejoin station. August 23, 1893. To proceed to Jersey City, N. J., for temporary duty. September 3, 1893. To rejoin station. September 9, 1893.

SPRAGUE, E. K., Assistant Surgeon. To proceed to Cairo, Ill., for temporary duty. August 26, 1893.

Society Meetings for the Coming Week :

MONDAY, *October 2d* : New York Academy of Sciences; German Medical Society of the City of New York (private); Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica Medical Library Association; Corning, N. Y., Academy of Medicine; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; Monmouth, N. J., County Medical Society (Freehold); South Pittsburgh, Pa., Medical Society; Chicago Medical Society.

TUESDAY, *October 3d* : Medical Society of Virginia (first day—Charlottesville); New York Obstetrical Society (private); New York Neurological Society; Elmira Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Medical Societies of the Counties of Broome (annual), Columbia (annual—Hudson), Orange (semi-annual—Goshen), and Schoharie (semi-annual), N. Y.; Medical Association of Northern New York (annual—Malone); Hudson (Jersey City), and Union (quarterly), N. J., County Medical Societies; Chittenden, Vt., County Medical Society; Androscoggin, Me., County Medical Association (Lewiston); Baltimore Academy of Medicine.

WEDNESDAY, *October 4th* : Mississippi Valley Medical Association (first day—Indianapolis); Medical Society of Virginia (second day); Medical Society of the County of Richmond (Stapleton), N. Y.; Society of the Alumni of Bellevue Hospital; Society of the Alumni of Charity Hospital; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Bridgeport, Conn., Medical Association; Philadelphia County Medical Society; Penobscot, Me., County Medical Society (Bangor).

THURSDAY, *October 5th* : Mississippi Valley Medical Association (second day); Medical Society of Virginia (third day); New York Academy of Medicine; Society of Physicians of the Village of Canandaigua, N. Y.; Brooklyn Surgical Society; Boston Medico-psychological Association; Washington, Vt., County Medical Society; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

FRIDAY, *October 6th* : Mississippi Valley Medical Association (third day); Practitioners' Society of New York (private); Baltimore Clinical Society.

SATURDAY, *October 7th* : Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

Obituaries.

WALTER VOUGHT, M.D.

DR. WALTER VOUGHT died in the New York Hospital on Sunday, the 24th inst. He had been ill for nearly five weeks with typhoid fever, which from the first had assumed a severe type. The end was rather sudden, from exhaustion.

Walter Vought was born January 8, 1862, in Buffalo. He studied for college in the Normal School of Buffalo. In 1882 he was graduated from the Sheffield Scientific School of Yale College, taking the degree of bachelor of philosophy.

He took his medical degree in 1885 from the College of Physicians and Surgeons (Columbia College), and subsequently

served as interne in the New York Hospital. Having finished his service as house physician in that institution, he spent a year in the study of general medicine, nervous diseases, and pathology in the clinics of Vienna and Heidelberg. On his return to America, in 1888, he became connected with the department of general medicine in the Vanderbilt Clinic, and subsequently with the clinic for nervous diseases in the same institution. He was afterward appointed chief of the nervous clinic, which position he held for a year, but resigned on account of the stress of work. He was the author of a work entitled *A Chapter on Cholera for Lay Readers*, recently published, which gave in a form readily understood by the non-medical mind the history, pathology, and treatment of the disease, with additional chapters on quarantine and disinfection.

He wrote several articles, some of which appeared in print: one on a Case of Syringomyelia, one on Several Cases of Acromegalia, and one on The Organisms found in the Blood in Malarial Fever. All these were the result of original investigation, and gave evidence of a mind whose powers of observation and acuteness of reasoning were far above the average. He was a fellow of the New York Academy of Medicine and a member of the New York Pathological Society, of the New York Neurological Society, and of the Medical Society of the County of New York.

He belonged to the Hospital Graduates' Club and to the Society of the Alumni of the New York Hospital, of which he was secretary.

Dr. Vought was medical director and physician in charge of the quarantine station at Fire Island during the summer of 1892, and showed himself at that time to be fearless and self-sacrificing. He spent a week with but six hours of sleep during the entire period and made order out of chaos in a manner remarkable for one who was entirely unused to such duties and responsibilities. He was a tireless student and searcher after scientific truth, and had acquired a mental equipment of professional knowledge such as few men attain to in a lifetime of study. He possessed unusual powers of organization, and the clinics of which he had charge always showed this in the methodical manner in which they were conducted and the judicious arrangement of material.

As a diagnostician Dr. Vought was acute to an unusual degree. His opinions were rapidly but accurately formed, and showed breadth of knowledge, especially in nervous diseases, in the diagnosis of which he excelled. He was a loyal friend, a sympathetic physician, and a pure and upright man. His many friends will deeply mourn his untimely end, and in losing him the medical profession of New York has lost a brother whose place it will be hard to fill.

Letters to the Editor.

DR. HAMMOND AND THE MEDICAL PROFESSION.

LEXINGTON HOTEL, CHICAGO, September 23, 1893.

To the Editor of the New York Medical Journal:

SIR: My respect for and my sympathy with the medical profession in America and my knowledge of their sentiments forbid me to regard Dr. William A. Hammond as their representative in the defense which he puts forward in your columns of September 16th of the practices of publicity-hunting by newspaper interviews, newspaper portraits, and of the use of and traffic in secret preparations, etc. I have in the course of recent travel received personally from many hundreds of

prominent and representative physicians in Milwaukee, Washington, Boston, Philadelphia, Chicago, Cincinnati, Detroit, and from all parts of the United States their cordial congratulations on the tone and substance of the addresses which I had the honor to deliver at Milwaukee and Washington. I have been assured on all hands of the entire sympathy of the great body of the profession in the views therein laid down and discussed. I should have been surprised, however, and perhaps disappointed, if they had not elicited some expression of pain and anger from certain quarters. "Let the galled jade wince, the withers" of the great American medical profession are, I am assured, "unwrung." Your correspondent, in an access of ethical agnosticism, assumes that the enumeration of ethical data as to medical conduct was or could be a reproof direct or implied to the medical profession of America. That is an unmerited insult which he addresses to his profession, and indicates a view which I apprehend to be special to himself. Let him enjoy the practices which he defends; I do not think he is likely to find much support or sympathy in them from medical men of good standing. His account of the position of the medical men in Great Britain is a parody undeserving of serious notice. As to myself, whom he favors with some personal abuse, I have been avowedly the scientific adviser to, but it is untrue that I have ever held any of the stock of the Apollinaris Water Company. As to his other trivialities, I was the guest of the Pan-American Medical Congress, and on entering its headquarters I registered in ceremonious form.

I have no desire to be honored among "the Pan-Anglians," "the Loyal Legion," the "Fat Men of America," and the other objects of lay interest with whom Dr. Hammond puts medical 'men on a par, and I do not agree with him that medical men should desire to share with them the honor of newspaper notoriety. I do not believe any details of my medical career have ever appeared in any lay paper.

I suggest that it might be desirable for Dr. Hammond to rely less upon his imagination for his facts, and not to assume to speak for a profession from which he has no sort of mandate, and which would, I am well assured, if consulted, repudiate both his advocacy and his methods of action and of expression. I am assured that he utterly misrepresents that profession both in his statement of principles which he ascribes to it and in his abuse of myself.

ERNEST HART.

TYPHOID FEVER IN OAKLAND, CALIFORNIA.

SAN FRANCISCO, September 7, 1893.

To the Editor of the New York Medical Journal:

SIR: The article, Typhoid Fever from a Dairy Farm, in the *Journal* of September 2d, in which Oakland, Cal., is said to have suffered so seriously, appears to rest on the authority of that highly sensational daily, the *San Francisco Examiner*, and the statements are entirely untrue. I am confident that there have not been a half-dozen cases of typhoid fever in Oakland in the last twenty months. There were a few cases of malarial fever in Oakland last June and July, probably thirty or forty, and a few persons were quite sick. I saw a few cases in Oakland, and quite a number of persons came to me in this city from Oakland suffering from malarial symptoms of a remittent type, which yielded promptly to anti-malarial remedies. The idea of over three hundred cases of typhoid fever in Oakland last June and July is most absurd. There are a number of localities in Oakland in which, after a little proper examination, malarial fever would be the first thing to suggest itself to a rational mind, and it was the people living in and about these places that were sick with a remittent fever. The object of this letter is, if possible, to prevent statistics being made up from such

unreliable sources as the *Examiner*, or even from the reports made to the health department of Oakland.

L. J. KING, M. D.

Proceedings of Societies.

FIRST PAN-AMERICAN MEDICAL CONGRESS.

Held in Washington on Tuesday, Wednesday, Thursday, and Friday, September 5, 6, 7, and 8, 1893.

(Continued from page 357.)

SECTION IN GENERAL MEDICINE.

The President, Dr. VICTOR C. VAUGHAN, of Ann Arbor, Mich., in the Chair.

The History of Malarial Fever in the Valley of the Orizaba, and its Relation to Typhus and Typhoid Fever.—Dr. G. MENDIZABAL, of Mexico, added another paper on the subject of malaria. He pointed out some clinical facts showing how the symptoms of typhus and typhoid were modified by the presence of malaria and other extrinsic and intrinsic agents. To successfully deal with malaria and associated diseases a positive diagnosis must be made, and for this the microscope was the sheet anchor.

Typhoid Fever.—Dr. W. C. DABNEY, of Virginia, read an abstract of a paper on this subject. The outbreak of fourteen cases of continued fever, which had occasioned the writing of the paper, had occurred at the University of Virginia between January 15 and April 1, 1893. A careful inspection and research into the sanitary conditions of the buildings and water supply had not resulted in the discovery of any cause for the epidemic in that direction. Next, the habits and outside associations of the five hundred and thirty students attending the college at the time had been closely inquired into, with negative results. The milk supply had next been investigated. The dairy at which the milk had been obtained was some distance from the University. At various times the milk had been tested and found free from added water, but careful inquiry had disclosed the fact that the cows' teats had been washed in water contaminated with sewage and probably infected with typhoid-fever germs. It was in evidence also that at least five of the fourteen persons having the fever had used milk at every meal. Of the fourteen cases, twelve had presented the typical features of typhoid fever; the other two had passed from under the writer's observation.

Dr. OLAISSONNE, of Virginia, said that there was always great difficulty in diagnosing continued fevers in malarial districts, and that for his part he was old-fashioned enough to confine his diagnosis of typhoid fever to those conditions that presented the pathognomonic sign of ulceration of Peyer's glands.

He was sorry that Dr. Dabney had had no opportunity of verifying his diagnosis by autopsy. As the history of the cases did not present typical symptoms, the speaker did not see how they could be classified. He said that in his part of the country cases of fever without distinctive features were called typho-malarial. Referring back to Dr. Risquez's paper, he thought that it would be a great step in advance if the pigment in the blood could be established as pathognomonic of malarial disease; it would do away with the difficulty in diagnosis. It was the speaker's practice to diagnose malarial fever by the administration of quinine; if the daily ingestion of twenty grains did not cause an evening reduction of temperature, he was not dealing with that disease.

Dr. J. W. LAERABEE, of Texas, said that last winter, in Louisiana, forty cases of typhoid fever had occurred from a milk supply. The contamination had been from the water, which had simply been used to wash the cans, and not to dilute the milk with. He also thought that in a malarial district it was almost impossible to make a diagnosis. His custom was to prepare the patients by a dose of calomel, and then to administer quinine; if no benefit was derived and the fever was continuous, the case was probably typhoid. He thought that the term typho-malarial was very misleading, and that to its door many disastrous results could be laid.

Dr. S. SOLIS-COHEN, of Philadelphia, said as there was no *a priori* reason why the name typho-malarial fever should not be used, he would like to hear what those present had to say about mixed infection. He thought that if the pigmentary masses in the blood could be decided upon as distinctively characteristic of malaria, the diagnosis by exclusion would be much facilitated. Thus far he had always been able to decide whether a given case was malarial or not by the quinine test. His method was to use a single hypodermic injection of quinine dichloride and urea. If the case was malarial, the proof would be the absence of the regular chill. He had used quinine chlorhydrosulphide, but he considered the dichloride superior for controlling the after-chill.

Dr. SIBBT, of Carlisle, Pa., explained the peculiarities of typhoid fevers in his community. During a recent epidemic of fever forty-two cases had been closely observed, and it had been found almost impossible to decide what the fever was. He could not say in cases of continued fever where or when the typhoid began or when it ended. For his part, he was inclined to believe that the poisons of continued and typhoid fever were one and the same thing, and that the intensity or mildness of the attack would depend upon the *vis medicatrix nature* of the individual.

Dr. WEST thought an important point would be gained when it could be decided whether or not there was a typhoid condition without typhoid fever, and *vice versa*, and also what was the real nature of the disease when patients walked about until intestinal perforation took place. In his section of the country there was a prevalence of atypical cases of typhoid, and he made it his practice to diagnosticate the cases with the aid of quinine. Where there was no benefit from the drug he excluded malaria. He did not think that two poisons could act simultaneously, and therefore did not believe in mixed infection.

Dr. WILCOX, of South Carolina, said that he did not attempt to diagnosticate atypical cases, but confined himself to classical symptoms. Whether it was a poison or not that did the mischief he did not know, but he was satisfied that combining influences very often masked symptoms in fevers, so that a positive diagnosis from clinical conditions alone could not be made.

Dr. ANDERS, of Philadelphia, thought that it was pretty safe if, during a mild or otherwise irregular endemic or epidemic of fever, a few cases of typical typhoid occurred, to call the disease typhoid fever.

Dr. VAUGHAN said that, while there might be such a thing as typho-malaria, or the combination of the two poisons, as yet it had never been demonstrated, and he was loath to believe in its existence. One theory in regard to the causation of typhoid fever was that the disease could not exist without the presence of a germ, which was always one and the same, and produced the specific poison. Another theory was that the germ was a modified form of the *Bacterium coli commune*, which under certain circumstances became virulent and produced typical typhoid fever. The speaker's theory was that typhoid was caused by any one of a number of germs that did not bear any resemblance to each other. And it was for this reason that the

symptoms were so varied, and the conditions so unlike in a given epidemic. He had just been through an epidemic of six hundred cases in Michigan, and had made very careful investigations, but was obliged to say that he had never as yet seen a typical case of typhoid fever, as set down in the text-books, and had never been able to discover the typical German germ. The drinking water that supplied the district infected during the recent epidemic had been carefully examined, and the Eberth germ had not been found, but a germ which differed from it very materially had been discovered in the spleens of persons who had died from the disease. The drinking water had also contained the same germ. The speaker did not believe that sharp lines could be drawn between the continued fevers, and different names applied to them meaning a difference in their pathology. He believed that the germs of typhoid were very widely prevalent, and that the only reason why the disease was not more prevalent was that the large majority of people were proof against their influence.

Dr. DABNEY did not think that typhoid fever was modified by the existence of malarial poisoning. As for text-book symptoms, he thought they were influenced by location; in his district, for example, it was rare to see the eruption. He was not prepared to say whether the Laveran and the Eberth germ could exist in the same person at the same time or not.

A Contribution to the Clinical Study of Prolonged Remittent Fever.—Dr. DAVID LOBO, of Caracas, Venezuela, added his experience to that of the other speakers as to fevers. He said that the normal type of malarial fever—the intermittent form—was rarely met with in Caracas, and its presence, when noticed, could generally be traced to genuine sources of infection. Close examination seldom disclosed any marked congestion of the liver and spleen in cases which had developed within the bounds of the city. The aspect and extraordinary course of the pyrexia were probably due to the corresponding variations in the power and quality of Laveran's corpuscles, to overpoisoning of the blood, or to some distinct element operating simultaneously with the paludal germ. The variations in temperature did not respond to any fixed law of recurrence; it generally ranged from 38°5' to 40°5' C., and dropped or rose unexpectedly. Remissions took place at any moment of the day. Intermissions might occur, but they could not be counted upon. Chills and sweating might be observed, but never as definite stages of the fever. The circulation and respiration did not exhibit any deviations except those induced by the reaction of the organism under the influence of abnormal heat. The appetite was either very poor or absent, with a tongue smooth, clean, and moist. The bowels were usually normal in action. Intense abdominal pain, meteorism, and profuse diarrhoea or obstinate constipation were indicative of some complication located in the intestines and not of the disease. Vomiting might occur, but it was not a feature. The urine was normal. There was, as a rule, an entire absence of nervous symptoms. The fever frequently ran its course entirely free from complications. Its duration ranged from fifteen to twenty days. The principal features of the disease were, then, the irregular temperature and the lengthened course. The main points by which protracted remittent fever could be discriminated from other malarial fevers were its uncommon course, its irregular temperature, the absence of marked stages of hepatic or splenic troubles, and its resistance to quinine. Between it and typhoid there could be no possible confusion; typhoid was cyclic in its career, was accompanied by intestinal lesions, presented peculiar eruptions, and, besides, was extremely rare at Caracas. The so-called typho-malarial fever exhibited typhoid symptoms, which were never present in ordinary remittent fever. The vomiting of black matter and albuminuria were so perfectly

distinctive of yellow fever that no mistake could be made in that direction. Pernicious fevers were distinguished by their short duration and characteristic aspect. In regard to prognosis, where complicating or intercurrent processes did not occur, a fatal issue was seldom to be feared. The fever might give rise to a special inflammation of the lung to which the term pseudo-pneumonia had been applied. Bronchial respiration was an early sign, and the crepitant râle was absent. Cerebral congestion was an occasional complication, and when it occurred the issue was fatal in nine cases out of ten. Hæmorrhage and acute peritonitis were apt to occur as secondary phenomena subsequently to ulceration of the digestive duct. The treatment of protracted remittent fever required the closest attention, and the symptoms were to be combated as they arose. Quinine as a drug was almost worse than useless in influencing the disease. Warburg's tincture had been found to be the most valuable remedy. Tonics should be prescribed from the first.

Dr. W. F. THAYER, of Baltimore, described the types of malarial fevers as found in his section of the country. He also gave a detailed explanation of the appearance of the micro-organisms found in the blood in the different forms of malarial fever. The main types of malarial fever with which the American physician was familiar each had its own organism, which could be traced through its different stages of development to the destruction of the blood-corpuscle.

Dr. Lobo wanted to emphasize the fact that he excluded the protracted remittent fever of Caracas from any other class, and made it a type by itself. Typhoid was almost entirely unknown in Caracas, and from malarial fever it was, by every means known to the diagnostician, absolutely dissociated. Just what combination of influences had caused the fever the speaker was unable to say.

(To be continued.)

SECTION IN GYNÆCOLOGY.

(Continued from page 383.)

Drainage of Ovarian Cysts where the Adhesions are such that it is Impossible to remove the Sac.—Dr. A. VANDERVEER, of Albany, whose paper had the foregoing title, called attention to the fact that the condition of patients who were to undergo an operation for abdominal tumors was often not ascertained with sufficient thoroughness. His plea was for a more complete knowledge of symptoms and more frequent examinations. Of course, the examinations must be of such a character that the patient's condition would not be made worse. In some cases the environments of the tumor could be so thoroughly mapped out that a severe operation would be almost a certainty. In such cases, and especially if the vital force of the patient had been much reduced, it had seemed to the speaker that the chances of recovery would be increased by not attempting to remove those portions of the tumor sac which were extensively adherent, but by attaching them instead to the abdominal wound and submitting them to drainage. Of course, this might also subject the patient to a certain amount of risk from sepsis, but it would minimize the shock of the operation and probably increase the chances of recovery.

Dr. C. P. NOBLE, of Philadelphia, believed that if one were attacking a malignant tumor of the abdomen and the adhesions were abundant, one should not attempt to do a complete operation, for the result would be a fatal one at no distant day in any event. If the disease was not malignant, he believed that an attempt should always be made to remove the entire diseased structure. One could be certain that death would be the inevitable result in some of the cases, especially those in which the

intestines were crowded forcibly upward by the tumor against the diaphragm and liver.

Dr. A. F. CURRIER, of New York, thought long-continued success in operating sometimes created false confidence, which was bad for patient and physician. Two classes of adhesions might be considered, in one of which the intestines or other viscera were seriously implicated functionally. These must be released at all hazards. In the other class there was an indurated mass in which the viscera might be imbedded. It was often well to leave this mass undisturbed. Leaving a portion of the tumor sac and draining it would follow.

Dr. A. LARTHOEN SMITH, of Montreal, thought the principle aimed at in the paper was that protracted operations were almost sure to be fatal.

Dr. I. S. STONE, of Washington, observed that in cases which offered little prospect of recovery there was sometimes unexpected success, because the operator had not attempted to do too much upon a very feeble patient.

Dr. E. W. CUSHING, of Boston, did not believe that any fixed time limit for operations was possible. Prolonged operations were not necessarily fatal.

Dr. VANDERVEER remarked that his subject did not include the consideration of malignant abdominal tumors, the entire removal of which was often impossible. He would also say that he was not in favor of the use of the thermo-cautery and solutions of iron for hæmorrhage in abdominal operations though they had been advocated by some authors.

The After-treatment of Celiotomy Cases with Special Reference to Shock and Septic Peritonitis.—This was the subject of a paper by Dr. EUGENE BOISE, of Grand Rapids, Mich. Three conditions following operation required intelligent action: hæmorrhage, sepsis, and peritonitis. Shock was a paresis of the sympathetic nervous system, primarily a super-irritation of the entire sympathetic system, intense stimulation of the entire sympathetic system with cardiac and arterial spasm. Its second stage was a paresis due to exhaustion of the heart. Hence in the first stage the indications were for hypodermics of codeine, nitrite of amyl, and nitroglycerin, with copious injections of hot water into the colon. In the second stage the indications were for strychnine, digitalis, and intravenous infusion of a hot saline solution. Prevention of sepsis prevented peritonitis; hence the peritoneal cavity should be made as clean as possible, and drainage and free catharsis were indicated after the operation, a tube or piece of gauze being employed for the former. After every abdominal section there was always a free flow of serum from the blood-vessels into the peritoneal cavity, depleting the vessels, and during the first few hours after such an operation there was paroxysmal abdominal pain, which might be very severe. This was due to irregular and spasmodic peristaltic action, the muscular coat of the intestine contracting unequally and sometimes causing obstruction. Again, as fluids were usually withheld from the patient immediately after an operation, this fact, with the intraperitoneal effusion referred to and, in some cases, profuse perspiration, resulted in depletion of the intestinal blood-vessels. Hence, in order to produce catharsis easily, the current must have ceased to flow from the blood-vessels toward the peritoneal cavity. The spasmodic contraction of the blood-vessels must be overcome, and the blood-vessels must be replenished. Serous effusion would cease after a few hours. Spasmodic contraction of the intestinal muscle might be overcome by a hypodermic injection of codeine, and the blood-vessels might be filled by injecting hot water into the rectum. Catharsis could then be readily effected.

Dr. E. W. CUSHING, of Boston, knew there was great difference of opinion concerning the usefulness of opium after ab-

dominal operations, but he felt that its function of relieving pain and stimulating the heart during the first few hours after an operation should not be overlooked or lightly considered. The obstruction of the bowel which so often followed abdominal operations might be due to imperfect preparation of the patient prior to the operation or might be a result of the operation.

Dr. TUCK, of Cambridge, Mass., said the temperament of a patient was a matter of great importance in preparing her for an operation, some women and some races being extremely sensitive, others not at all. This fact had a bearing upon the prognosis of operations. Great stress should be laid upon the importance of thoroughly clearing out the intestinal canal prior to an operation, calomel and salts being freely used. The salines might be injected under the skin before an operation, with prompt and beneficial result. The condition of the heart should also be attended to before operating.

Dr. C. P. NOBLE, of Philadelphia, believed that the best way to treat shock was to prevent it as far as might be. Important measures were to keep the temperature of the operating room at from 75° to 80° F., to keep the patient well covered with blankets, and to use no wet towels on the body. After the operation, if the heart was weak, large hypodermics of strychnine should be used—as much as a fifteenth of a grain every three or four hours—until muscular twitching occurred. The speaker always gave an eighth of a grain of morphine immediately after an operation if pain was present. Another important point was to keep the patient warm and dry after the operation, the perspiration being frequently wiped away and the limbs rubbed.

Dr. R. T. MORRIS, of New York, believed that no chemicals should be used in the abdominal cavity, as they injured the epithelium of the peritoneum and encouraged the formation of adhesions. A normal saline solution was the only fluid which could be used without harm.

Dr. J. H. CARSTENS, of Detroit, suggested the valuable aid to be obtained by the administration of turpentine, in doses of ten to fifteen drops, when the abdomen began to be distended.

Dr. BOISE did not favor the use of strychnine immediately after an operation. The nitroglycerin and nitrite of amyl were given to relax the arterioles.

(To be concluded.)

Book Notices.

A Manual for Boards of Health and Health Officers. By LEWIS BALCH, M. D., Ph. D., Secretary State Board of Health of New York. Albany: Banks & Brothers, 1893. Pp. 4-5 to 242.

This manual is intended to serve as a practical guide for health officers and health boards, especially in the State of New York, as it is based on the public health laws of that State. The first chapter defines the powers and duties of the State board of health; the second chapter, those of local boards of health; the third chapter, the duties of the health officer; the fourth chapter, the relations of doctors, clergymen, magistrates, and others to local boards; and the fifth chapter, what constitutes a nuisance, the modes of procedure necessary to abate nuisances, and the power to enforce penalties; and the sixth chapter is devoted to general sanitary regulations regarding infectious and contagious diseases, disinfection, and the forms of certificates for reporting births, marriages, and deaths. The volume contains as an appendix a copy of the act, passed in 1893, relating

to the public health. It will undoubtedly prove useful to the health officials of counties, municipalities, villages, and towns.

Nursing: its Principles and Practice. For Hospital and Private Use. By ISABEL ADAMS HAMPTON, Graduate of the New York Training School for Nurses attached to Bellevue Hospital; Superintendent of Nurses and Principal of the Training School for Nurses, Johns Hopkins Hospital, Baltimore, Md., etc. Illustrated. Philadelphia: W. B. Saunders, 1893. Pp. ix-17 to 484. [Price, \$2.]

The authoress of this volume has apparently had abundant experience in the duties of nursing, and her supervisory position has familiarized her with the requisites essential to make a qualified nurse. She has treated her subject in a clear and comprehensive manner, and a nurse familiar with the practice taught by this book will be an orderly, unobtrusive, and helpful assistant to the physician. The only error we note is on page 132, regarding the need of friction during the Brand bath; it can hardly be the custom at the Johns Hopkins Hospital to use friction in the tub only in instances in which there is much nervous tremor or blueness.

There are no important omissions in the work, and we believe it will have a wide sphere of usefulness.

On the Nature and Treatment of Talipes Equino-varus or Club-foot. By BERNARD E. BRODHURST, F. R. C. S., Surgeon to the Royal Orthopaedic Hospital, etc. London: J. & A. Churchill, 1893. Pp. 60.

This treatise, originally published in 1856 and republished in 1876, is again presented to the profession with some additions and rectifications. The author lays special stress upon the fact that tarsotomy or tarsetomy in young children is absolutely unjustifiable, a fact that has been generally accepted by orthopaedic surgeons for years past. The reference to prothetic appliances and the conditions that demand special apparatus might have been more extensive in a monograph such as this.

Ueber Gasphlegmonen. Von Dr. EUGEN FRAENKEL, Prosektor am neuen allgemeinen Krankenhause zu Hamburg. Mit drei chromolithographischen Tafeln. Hamburg und Leipsic: Leopold Voss, 1893. Pp. 56.

In this little monograph the author reviews the literature of emphysematous gangrene and malignant edema, and he then describes his own investigations made to determine the character of the infection. The latter, he finds, is caused by a particular micro-organism, the *Bacillus phlegmones emphysematosus*. The work is a valuable contribution to the literature of bacteriology.

Die Zaraath (Lepra) der hebräischen Bibel. Einleitung in die Geschichte des Aussatzes. Von G. N. MÜNCH, Ord. O. Professor der Universität zu Kiew. Mit 2 Lichtdrucktafeln. Hamburg und Leipsic: Leopold Voss, 1893. Pp. 167. [Preis, 6 M.] [Dermatologische Studien. Herausgegeben von Dr. P. G. Unna.]

This monograph is the sixteenth part of the *Dermatologische Studien* edited by Dr. P. G. Unna. The author has carefully reviewed the references to leprosy in the works of the Greek fathers in medicine and in the Bible. He then reviews later authorities on the subject, dividing the authors into three groups: first, those that consider zaraath and leprosy as identical; second, those who consider that other skin diseases besides leprosy were included in the Biblical references to zaraath; and third, those that consider zaraath and leprosy as distinct dis-

eases. He then presents an interesting historical, geographical, and philological study of his theme, that bears every evidence of wide research and able criticism. The work will be found interesting by all students of the history of medicine as well as by dermatologists.

BOOKS, ETC., RECEIVED.

Baden-Baden und seine Thermen. Von Dr. med. W. Henry Gilbert, Hausarzt des Sanatoriums und Kurarzt in Baden-Baden. Wien und Leipzig: Wilhelm Braumüller, 1893. [Braumüller's Bade-Bibliothek. Pp. viii-169.] [Preis, M. 2.50.]

Die Krankheiten der Mundhöhle, des Rachens und des Kehlkopfes. Mit Einschluss der Untersuchungs- und Behandlungsmethoden. Für praktische Aerzte und Studierende. Von Dr. Albert Rosenberg, I. Assistenten an der Universitätspoliklinik für Hals- und Nasenkrankheiten in Berlin. Mit 178 Abbildungen und einer lithogr. Tafel. Berlin: S. Karger, 1893. Pp. x-329. [Preis, M. 8.]

Therapeutics of Generative Diseases of the Spinal Cord. By CURRAN POPE, M. D., Louisville, Ky. [Reprinted from the *Journal of Bacteriology*.]

Transactions of the Association of American Physicians. Eighth Session, held at Washington, D. C., May 30, 31, and June 1, 1893. Vol. VIII.

Transactions of the Texas State Medical Association. Twenty-fifth Annual Session, held at Galveston, Texas, May 2, 3, 4, and 5, 1893.

Circumcision: its Advantages and how to perform it. By M. Clifford, L. R. C. P. Lond., M. R. C. S. Eng. London: J. & A. Churchill, 1893. Pp. 23.

Memorie dell' Accademia medico-chirurgica di Ferrara. Anni 1892-'93.

Report of Ten Years' Service at the Philadelphia Dispensary for Skin Diseases. By Henry W. Stelwagon, M. D.

Local Boards of Health in the State of New York. Board of Health, State of New York.

Miscellany.

The New York State Medical Association will hold its tenth annual meeting on Monday, Tuesday, Wednesday, and Thursday, October 9th, 10th, 11th, and 12th, at the Mott Memorial Hall, 64 Madison Avenue, New York, under the presidency of Dr. S. B. Wylie McLeod. The announcements on the programme include the following: Address of Welcome, by the chairman of the Committee of Arrangements, John G. Truax, M. D., of New York County; Address by the President; Address: The Medical Work of the Association during its First Decade, by John Shrady, M. D., of New York County; Address: The Surgical Work of the Association during its First Decade, by Stephen Smith, M. D., of New York County; Report of Eight Cases of Placenta Prævia, by Zera J. Lusk, M. D., of Wyoming County; Penetrating Wound of the Anterior Fossa through the Orbital Plate of the Frontal Bone—Recovery, by Zera J. Lusk, M. D., of Wyoming County; The Treatment of Epithelioma and the Canceroid Ulcers by Topical Application, by Nelson J. North, M. D., of Kings County; The Prevention of Disease, by James G. Porteous, M. D., of Dutchess County; Discussion on Lesions of the Pleura (to be opened by John Shrady, M. D., of New York County, propounding the following questions: Question 1. What are the factors of pleurisy? Its forms and contributive conditions? What are the patho-

logical changes in a case of progressive pleurisy ending in recovery? To be spoken on by Frank W. Ross, M.D., of Chemung County, and William McCollom, M.D., of Kings County. Question 2. What are the points of differential diagnosis in pleurisy and other affections of the chest? To be spoken on by Edward F. Brush, M.D., of Westchester County, J. Blake White, M.D., of New York County, and John G. Truax, M.D., of New York County. Question 3. What is the treatment of empyema, with relative value of aspiration, rib resection, and free opening with tube drainage? To be spoken on by M. K. Hogan, M.D., of New York County, and Charles A. Leale, M.D., of New York County. The Surgical Treatment of Pulmonary Cavities, by N. P. Dandridge, M.D., of Cincinnati, Ohio; Remarks on Fermentative Dyspepsia, by Austin Flint, M.D., of New York County; The Open Treatment of Tuberculous Disease of the Joints, by T. M. L. Chrystie, M.D., of New York County; Bloodless Amputation at the Hip Joint—Report of Cases operated on by the Author's Method, by John A. Wyeth, M.D., of New York County; Report of a Case of Osteotomy of Both Femora for the Relief of Deformity following Ankylosis of the Hip Joints, by Reginald H. Sayre, M.D., of New York County; Address: The Obstetrical and Gynecological Work of the Association during its First Decade, by George Tucker Harrison, M.D., of New York County; Rare Forms of Gout and Rheumatism, by Sir James A. Grant, of Ottawa, Canada; Treatment often indicated after Trachelorhaphy, by William H. Robb, M.D., of Montgomery County; R, by Henry D. Didama, M.D., of Onondaga County; Ten Years' Experience in the Treatment of Cataract, by Alvin A. Hubbell, M.D., of Erie County; The Treatment of Enteric Fever, by Gustavus Eliot, M.D., of New Haven, Conn.; Voluntary Commitment of the Insane to Asylums, by W. D. Granger, M.D., of Westchester County; Surgical and Pathological Memoranda, by Donald McLean, M.D., of Detroit, Mich.; discussion on the Treatment of "Appendicitis" (to be opened by Frederic S. Dennis, M.D., of New York County, propounding the following questions: Question 1. What proportion of cases of "appendicitis" end in resolution? Question 2. What class of cases require immediate operation? Question 3. What class of cases do not require immediate operation? These questions will be answered by R. N. Cooley, M.D., of Oswego County, Donald McLean, M.D., of Detroit, Mich., W. S. Tremaine, M.D., of Erie County, Joseph D. Bryant, M.D., of New York County, and John W. S. Gouley, M.D., of New York County); The Male Catheter, with some Observations upon the Proper Mode of Introduction into the Bladder, by Douglas Ayres, M.D., of Montgomery County; Researches on the Efficacy of Vaccinia after Typhoid Fever, by William Finder, Jr., M.D., of Rensselaer County; Reflections on the Need of Close Observation of Disease and upon the Value of Hygienic Therapeutics, by H. Ernst Schmid, M.D., of Westchester County; A Unique Case of Traumatic Tetanus, with Generalization—Recovery, by John G. Orton, M.D., of Broome County; A Case of Puerperal Blindness, by Darwin Colvin, M.D., of Wayne County; A Plea for the Non-operative Method of Treating Dysmenorrhœa, Pelvic Inflammation, and Pelvic Abscess, by T. J. McGillicuddy, M.D., of New York County; An Additional Note on Nephrotomy and Nephrectomy, by E. D. Ferguson, M.D., of Rensselaer County; Fifty Operations for Laceration of the Cervix Uteri, by J. B. Harvie, M.D., of Rensselaer County; Brief Comments on the Materia Medica, Pharmacy, and Therapeutics of the Year ending October 1, 1893, by E. H. Squibb, M.D., of Kings County.

The Strychnine Treatment of Snake-bite Poisoning.—In the August number of the *Indian Medical Gazette* Surgeon-

Captain J. C. Vaughan, of the Indian Medical Service, relates the case of "Hazari Lal, aged about twenty-four, a Hindu of good physique, a convalescent prisoner in the jail hospital at Monghyr, was lying asleep on the ground near his bed. It was a hot night with but little breeze, and he had left his bed to sleep opposite the window, the gratings of which reach the level of the floor. While dozing he felt a snake crawl over him, and reached his hand down to draw his blanket close to him. As he did so the snake seized him by the ulnar edge of the hand and held on to him so firmly that he had to tear it off him before he could fling it away. The snake unfortunately escaped; but the man says it was about as long as his arm. He cried out that something had bitten him, but was apparently not very much alarmed, as he tried to compose himself to sleep. Pain in the limb becoming severe, he called for help and asked for water, but apparently in a very short time he became unable to speak on account of the great pain and sense of constriction in his throat. The jailer and the native doctor both appeared and could get nothing much out of the man, when they noticed that he was salivating freely. This was at nearly 10 P. M., and the man had been bitten fifteen or twenty minutes previously. I was sent for at once, but was unfortunately out, and it was not until nearly 11.15 that I saw him. He was then lying nearly on his back with his eyes half open with a drowsy look in them. Jaws apparently set, retching frequently but rather weakly, while a thick frothy saliva flowed rather copiously from his mouth. While I was watching him he had a convulsive seizure followed in a minute or two by a second one. Pulse, 84, quiet and regular. Respiration could not be very well taken on account of the frequent retching. On examination, one distinct deep puncture and a scratch close to it were found on the inner edge of the right hand above and behind the hypothenar eminence. He also complained by signs of a painful sense of constriction of the throat and chest, and was quite unable to speak, though trying to do so. A one-per-cent. solution of sulphate of strychnine in water and dilute acid was quickly prepared, and at 11.20 P. M. I gave him fifteen minims hypodermically into the right forearm. This seemed a large dose, but the case was obviously *in extremis* and a desperate one. By 11.30 there seemed no difference except that he was, perhaps, a little more awake, so ten minims more were injected. By 12 midnight he seemed to suffer less from exhaustion and to notice things little more, but was still very drowsy and quite unable to speak. Another injection of five minims was now given. By 12.10 A. M. he was much in the same condition and continuing drowsy, so ten minims were again injected; still salivating freely. At 12.25 A. M. the following note was made: Retching very much less; sitting up; constriction of the throat much less, but makes signs to intimate that he can't speak because of it. Is still drowsy; pulse, 84; respiration regular; 12.26, seems improving, but salivating still a little. At 12.30 again tries to sit up; makes signs that his head is swimming, but on being questioned signs that this not so bad now; constriction in chest not so bad now, still can't speak; salivation practically ceased.

"At 12.40 another fit of retching, and after it an unsuccessful attempt to pass urine. Another hypodermic of five minims given. He had now had in all forty-five minims of a one-per-cent. solution of strychnine in the course of an hour and twenty minutes, and there has not been as much as a trace of tetanic spasm. On the contrary, the convulsive seizures noted before the exhibition of strychnine absolutely ceased with the first dose of the drug.

"1.20 A. M.—Has had about fifteen minutes' sleep, and has now just passed about eighteen ounces of clear urine. Complaints of tingling sensations in the limbs and mouth (makes

signs to that effect and answers to leading questions). His head is better now, not swimming; lies down to rest.

"1.45 A. M.—Becoming restless again and inclined to retch. Appears uneasy. Five minims of strychnine solution again injected relieved him at once.

"2.30 A. M.—Has been asleep till a little while ago. Is again becoming restless and inclined to vomit and retch. Strychnine injection of five minims repeated. Again relieved at once.

"3.05 A. M.—Has been asleep since last injection, but is now retching again. Injection (five minims of strychnine solution) repeated.

"5.20 A. M.—Seems wonderfully better, much stronger, can stand by himself, speaks clearly for the first time, no choking or constriction in the throat, but a tingling sensation down the middle line of the chest. Has had a sound sleep since the last injection. After this his recovery was complete, and without further interruption. His appetite was rather poor that day (24th June) and the tingling in the chest did not wear away till the evening of the 24th. There was no pain or swelling at the seat of the bite after 3 A. M. on the 24th."

The patient had in all sixty minims of a one-per-cent. solution of strychnine given in the course of three hours and forty-five minutes, and throughout the whole course of the case, says Dr. Vaughan, there was not one single trace of tetanic spasm, "and that in spite of the fact that I began with the huge dose of $\frac{1}{2}$ of a grain, followed in ten minutes by gr. $\frac{1}{10}$ more. The ordinary B. P. dose for hypodermic injection is $\frac{1}{10}$ gr. In all, this patient had $\frac{3}{2}$ of a grain hypodermically, and not only were there no tetanic spasms, but the restlessness and retching were positively relieved, and sleep followed at any rate, even though we may refrain from saying that it was induced. I shall certainly give strychnine a further trial."

Hæmaturia in Snake-bite Poisoning.—In an article published in the August number of the *Australasian Medical Gazette* Dr. A. Mueller, the well-known advocate of the treatment of snake-bite poisoning with large doses of strychnine, says:

"Within the last few months three cases of hæmaturia after tiger snake-bite have been brought under my notice, in the first one of which, published by Dr. Skinner and myself in the March number of this journal, the microscopical examination of the scanty, dark-brown urine containing blood casts, large masses of cloudy granular epithelial casts, and debris, and numerous shrunken red corpuscles, placed a serious affection of the kidneys beyond doubt. Feoktistow also observed gross anatomical changes in the kidneys of poisoned cats, and further found their urine to produce in small quantities violent toxic effects when injected subcutaneously. We may therefore assume that the snake poison is eliminated through the kidneys undecomposed, or at least but little changed in its effects.

"It appears strange that so important a symptom as hæmaturia has not been previously observed and recorded here, and only within the last few months attracted my attention; but the reasons are obvious. In the first place, the busy practitioner, when attending a case of snake-bite, which usually ends within a short time in recovery or death, has his attention so much riveted by the more patent and alarming symptoms of paresis and paralysis that the conditions of the kidneys and urine are apt to be overlooked, in all acute cases at least, which form by far the greater number. Another reason that caused us to overlook the urine was that we did not expect to find anything in it, especially not blood, since the hæmorrhagic process that marks the viperine poisoning in India is generally absent in poisoning by our colubines, and only indicated exceptionally by bloody vomiting.

"The importance, therefore, of bloody urine in persons bit-

ten by tiger snakes can not be overrated. If it is apt to occur at an early stage, as one of the cases I shall submit undoubtedly proves, and if the process by which the blood is forced through the renal capillaries is the same as in other organs—namely, diapedesis causing both blood and epithelial casts to appear in the scanty secretion of the kidneys—our patients are, in any case of tiger snake-bite, in imminent danger of having these important organs blocked, and the principal, if not the only, door shut by which the insidious enemy can be ejected. Some of it may be thrown out by vomiting and purging, but to initiate either or both in a person collapsing from diminished motor-nerve force does not recommend itself as rational treatment. It is equally hopeless to produce an efficient diaphoresis. When the skin is cold and blanched, and we can not force the blood to the surface because it is accumulating in the abdomen, pilocarpine injections, which have been suggested, are not likely to be of any service. Our only chance of preventing the kidneys from being destroyed is to prevent the dilatation of their capillaries, which gives rise to diapedesis. Once the latter has taken place, the tubes are filled with blood and their epithelium is largely cast off, all remedial measures would appear to be futile.

"In the early and vigorous use of strychnine injections, keeping the renal arterioles and capillaries contracted and the circulation open, we have the only means of coping successfully with the conditions that bring about hæmaturia in snake-bite. It will be seen from the account of the two cases I shall submit that strychnine was not administered at all in quantity sufficient to prevent the mischief. In the first one, in fact, it was not used at all until hæmaturia had set in, the symptoms being so undecided that the young practitioner, who, unfortunately, had never seen a case of snake-bite before, did not feel justified to inject strychnine until his attention was called to the blood in the urine, and shortly afterward coma set in. Then he injected strychnine in very small doses only. In the second case only one ten-minum injection was used. Both ended fatally.

The first case is that of a girl of nine years, bitten by a large tiger snake on the leg while going to school in the morning. She was immediately conveyed to the nearest medical man, distant twenty miles; but, traveling in a dray over rough mountain roads, did not reach the latter until past midday, and then showed so little signs of poisoning—being quite conscious and able to walk—that all treatment was omitted pending more decided symptoms; those she showed—cold and pale skin, quick pulse, and general lassitude—being explainable as mere effects of fright. She was kept under close observation at the residence of the gentleman—a very conscientious and painstaking young practitioner. During the afternoon she voided a *pint of almost pure blood from the bladder*, but scarcely any urine, though frequent mildly stimulating drinks were given to her. At 4 P. M. she suddenly became very drowsy, and rapidly sank into coma. Very small doses of liq. strychnine were then injected at half-hour intervals, which somewhat roused her, but she quickly became unconscious again after each injection, and when slight twitchings of the platysma took place, the further use of strychnine was thought to be risky, and the child died in a comatose state before morning.

"This case, like that of Miss D., shows the irregular and insidious action of snake poison once more to perfection. It first concentrated on the vaso-motor centers, leaving all the other ones comparatively free for more than seven hours, and then suddenly invaded the cortical centers of the hemispheres, but not until it had effectually blocked the kidneys and rendered escape of its victim, even under the most energetic treatment, all but hopeless. If the idea of Professor Virchow, that every blood corpuscle has a consciousness of its own and acts with a

certain degree of intelligence, is the correct one, we might almost feel tempted to grant the same faculties, cunning and malicious in the highest degree, to the subtle ophidian venom.

"The second case of undoubted hæmaturia following tiger snake-bite occurred at Echuca as late as the 1st of May last, the victim being Francis Stanton, alias Professor Hullar, the snake charmer, aged forty-one years. He was bitten on the right hand during one of his public performances by a large tiger snake, nearly five feet long, which he had caught on the previous day. Dr. Warren has kindly furnished me with notes of the case, of which I give, for brevity's sake, abstracts. Immediately after being bitten, Stanton took his own remedies—to wit, a large dose of calomel and some ammonia in brandy, which he alleged to have frequently cured him. He then sent his assistant in the snake charming business for a cab to take him to his hotel; but, before the latter returned and hardly a quarter of an hour after the bite, he suddenly collapsed and fell down unconscious, and by the bystanders supposed to be dead. They carried him at once to Dr. Eakins's surgery, where Dr. Warren, assistant to the latter, at once incised the punctures and injected ten minims of liq. strychninæ P.B., the professor, who had come round from the swoon, all the time objecting to the treatment. He revived sufficiently to be able to walk, and Dr. Eakins having arrived, he was allowed to walk to his hotel, a distance of about two hundred yards.

"He was not again heard of until the following day (Tuesday), when he came to the surgery to have his hand dressed, which was very much swollen. Dr. Warren writes: 'He next visited the surgery about 11 A. M. on Wednesday, and appeared so bad that I ordered his removal to the hospital. *He was passing bloody urine*, was cold and confused, and had been drinking both before and after the bite. Dr. Eakins saw him at the hospital shortly after his admission, when he ordered hot turpentine stupes over the loins, one ounce of brandy in Liebig's beef tea every three hours, and ten-grain doses of chloral and bromide every four hours, as he was very restless. Large (?) quantities of bloody urine were being passed, as well as black tarry motions.'

"When last seen by Dr. Eakins, at 11 P. M., he seemed much improved, but still had a very anxious look about him. Dr. Eakins ordered the matron to look after the patient herself, and to send for him at once on any change occurring. The change came at 4.30 A. M., and on Dr. Eakins's arrival the patient had just died, complaining of intense pain and constriction across the chest, with a fearful sense of smothering and oppression.

"In this interesting case we see the 'harmless' snake poison killing a man in the prime of life after lingering fifty-six hours and a half in his system, principally invading the vaso-motor and finally giving the *coup de grace* by sudden paralysis of the respiratory centers. There is only one point in Dr. Warren's account that does not square with the observations in the other two cases of hæmaturia—namely, the alleged large quantities of bloody urine. Large quantities of blood in the urine would be more feasible, for when the kidneys bleed from any cause their secretion is generally impeded. Unfortunately for the cause of science, an autopsy in this case does not appear to have been made. Three fatal cases of hæmaturia within a few months justify the suspicion that this insidious complication is much more frequent in snake-bite than we have hitherto supposed, and that it renders the prognosis in any case very ominous. We can only prevent but not cure it, and the only chance we have of preventing it is the early and vigorous use of the only antidote we possess."

The Frequency of Pyæmia without an External Wound.

—In the September number of the *Glasgow Medical Journal*

Dr. John Lindsay Steven cites the following passage, on a disease that has been termed periosteal abscess, acute necrosis, and malignant periostitis, from Wilks and Moxon's *Lectures on Pathological Anatomy*:

"When the inflammation is extensive and severe, pus forms under the periosteum, and raises that membrane off the bone to form an abscess around the bone. Thus arises a terrible and very dangerous disease, which is not very uncommon; it nearly always occurs in children or young persons, and is usually ascribed to some injury which is generally not severe. The danger that attends it arises from its disposition to set up a very grave form of pyæmia, during which abscesses occur in the heart and kidneys much more often than in pyæmia from any other cause. The disease is not usually limited to the periosteum; indeed, some French pathologists have said that necrosis of the bone does not occur unless the medullary membrane is implicated. Certainly section of the bone usually reveals an inflamed state within; lymph and pus are found within the medullary cavity and cancelli: yet in many cases this is not so, but the bone is dead, while the interior exhibits no sign of former inflammation. Sometimes the disease kills very rapidly, as, for instance, in six or seven days; indeed, before pus has time to form in large quantity. The periosteum is then found detached, and the bone separated from it by a dirty, brownish, turbid fluid, consisting of pus in which some altered blood is mixed. If the patient live longer—say for two or three weeks—a large quantity of pus is found around the bone, the bone itself being quite naked and white, or, more strictly, of the color of milk of sulphur. The disease generally stops at the epiphyses, but not always; it very rarely, however, reaches the joints. It nearly always attacks one of the long bones, more generally of the lower extremity, but it has been known to affect the pelvic bones, pterygoid process, etc. We have seen it limited to the middle phalanx of one finger in a case rapidly fatal with the characteristic pyæmia."

Dr. Steven then gives an account of a post-mortem examination made by him in a case of the kind that had proved fatal by the supervention of pyæmia. It was the first case he could remember in over eight hundred autopsies, but after he had sent his notes to the printer he encountered another almost precisely like it, and he says that he remembers a case in which, eleven years ago, Dr. Joseph Coats made the necropsy.

Brown-Séquard's Elixir.—As this eminent physiologist is reasserting with great confidence the therapeutical efficacy of testicular and other glandular preparations, it may be interesting to cite negative evidence on the subject. *Lo Sperimentale* (of Florence) quotes from the *Riforma Medica* the results of a long series of experiments with the "liquido testicolare di Brown-Séquard," undertaken by S. Massalongo. He concludes that the testicular liquid of young and healthy mammals, injected hypodermically, has not the slightest effect upon the human organism; that the trifling and transitory modifications of circulation, respiration, temperature, and muscular power are explicable by the excitement and tension of the subject's mind; that any rare and transient improvement observed in the treatment of various organic diseases by this method was due to suggestion and the influence of imagination, to which causes alone is to be attributed the cure of some cases of hysteria and neurasthenia.—*Dublin Journal of Medical Science.*

The City (Charity) Hospital.—An examination of candidates for appointment on the house staff took place on Wednesday of last week, and the following gentlemen became junior assistants: Dr. G. P. Shears, Dr. G. G. Holladay, Dr. Benjamin Touans, Dr. James I. Irvin, Dr. Joseph Grice, Dr. Anton Heger, Dr. S. G. Frank, and Dr. James McDermott.

CLINICAL CONTRIBUTION TO
THE STUDY OF AURAL SYPHILIS.*

By MAX TOEPLITZ, M.D.,

AURIST TO THE NEW YORK OPHTHALMIC AND AURAL INSTITUTE;
SURGEON TO THE NEW YORK NOSE, EAR, AND THROAT DISPENSARY;
AND LARYNGOLOGIST TO THE MONTEFIORE HOME.

AURAL syphilis may be manifested during the secondary and tertiary stages, and some rare cases also even of primary induration of the auricle have been reported.

Secondary affections are, as a rule, transmitted from the pharynx and nasopharynx through the Eustachian tubes into the middle ear, or they appear in the external meatus as condylomata or ulcers.

Tertiary syphilis is characterized by chronic inflammation of the periosteum of the labyrinth with subsequent hyperostosis or exostosis of the petrous bone, or of the cavities of the labyrinth, leading to stenosis or even occlusion of the latter.

All cases, however, exhibiting syphilitic affections of the labyrinth are due to hereditary or to acquired syphilis of long standing.

The case which I have but recently observed is remarkable by the fact that the labyrinth was affected primarily in the course of a freshly acquired case of syphilis, and that the aural affection began simultaneously with the appearance of roseola.

The patient, a physician, aged forty-one, married, of excellent repute and standing, presented himself at the Aural Department of the New York Ophthalmic and Aural Institute on August 1, 1892, with the only complaint of deafness in the left ear, other symptoms being absent.

Otoscopy revealed moderate congestion of Shrapnell's membrane, which seemed to have disappeared on the following day upon application of two leeches to the tragus. Politization, used for diagnostic purposes, did not improve the hearing.

Hearing power, horologium, A. S. = $\frac{\text{contact}}{36''}$; A. D. = $\frac{1}{8}$.
On August 2d hearing had improved to A. S. = $\frac{1}{8}$.

August 3d.—Hearing worse; leeches to the mastoid.

On the fourth day of observation the right ear, which had been endowed with very acute hearing, had also become affected.

The examination with tuning forks, which did not give any distinct results in the very beginning as to the relation of bone and air conduction and seemed to be leaning more toward a decrease of bone conduction, revealed on August 4th positive Rinné in both ears, but there existed almost as much bone conduction as air conduction, the former having decidedly decreased.

My diagnosis of otitis interna was now fully justifiable, on account of the sudden development of deafness and the great difference of the course of the affection from that of otitis media.

In order to ascertain the aetiology, I questioned the patient about former attacks of syphilis, but with entirely negative result. After repeated inquiries for fresh lesions, the doctor pre-

sented the middle finger of his left hand, which bore in the center a round, hard tumor of the size of a large cherry, representing a genuine, primary chancre contracted during gynecological examinations. Dr. Sigmund Lustgarten confirmed my diagnosis of syphilis. At the same time, pharyngeal mucous patches and a beginning roseola were found. Energetic treatment with inunctions of blue ointment were immediately resorted to, and injections of pilocarpine were independently made by the patient.

The further course of the affection ran as follows:

10th.—Patient experienced a tendency to fall upon rising in the morning, and especially when awakened out of sleep.

The walls of the building seemed shaking. He felt once or twice, for a minute, as if he would like to put his hands against the wall, but the phenomenon was not very marked.

16th.—Hearing power, horologium, A. U. = $\frac{\text{contact}}{36''}$. Tuning fork perceived as above.

Ordinary conversation is well understood, but the patient has to pay strict attention.

Whisper: A. D. = $\frac{8'}{20''}$; A. S. = $\frac{15'}{20''}$.

Conversation: A. D. = $\frac{10'}{60''}$; A. S. = $\frac{6'}{60''}$.

17th.—Result of examination with tuning forks unchanged. Weber's experiment: Tuning fork perceived in either side equally well. Tuning forks, both high and low, are perceived when placed upon right mastoid in A. S., but when right ear is closed, in A. D. R. E. does not hear all the high notes of the piano above g'.

L. E. does not hear all the high notes of the piano above last e; the high notes were perceived as mere taps without the faintest musical sound.

October.—In the beginning of October the hearing of A. D. was almost normal, A. S. somewhat improved.

November 23d.—Whisper: A. S. = $\frac{15'}{20''}$.

Watch: A. S. = $\frac{4''}{36''}$.

Conversation: = $\frac{60}{60''}$.

Rinné: A. S. negative.

Weber's experiment: Diapason vertex not perceived in either ear.

High and low tuning forks equally well perceived. T. F. placed upon right mastoid, best perceived in A. S. Hearing for the watch, whisper, conversation, and tuning fork, and musical hearing were normal.

Mucous patches of the soft palate were not quite healed.

The special features of this case are as follows:

1. The affection of the labyrinth occurred after the appearance of the pharyngeal mucous patches and simultaneously with the appearance of roseola.

2. The aural lesion took place during the secondary stage without attacking the middle ear.

3. The diagnosis of syphilis was made from the ear.

It may be doubted that the affection was located in the labyrinth, and, in its stead, the outer wall of the labyrinth, and more especially the region around the oval window may be preferred for its location. The entire course of the disease, however, contradicts such an assumption, and also the suddenness of the beginning, the well-nigh entire absence of inflammatory signs in the membrana tympani, the mutual relation of both ears during the attack, the relation of bone conduction and the vertiginous attack—all speak in favor of labyrinthine disease.

The pathological changes produced by the syphilitic

* Read before the Otological Section of the Pan-American Medical Congress held at Washington, September 5, 1893.

poison, which entered the lymphatic and blood current of the labyrinth from the pharynx through the aqueduct and the blood-vessels, probably consisted in inflammatory alterations of the membranous portion, the periosteum and the surrounding lymph of the vestibule, and the first turn of the cochlea, with an increase of cellular elements and hæmorrhages. All these changes disappeared after energetic antilutetic treatment.

I have looked over the literature on the subject and have not found a similar case of labyrinthine disease due to secondary syphilis in its early stage without implicating the middle ear.

Politzer* only mentions in general that "in affections of the middle ear due to syphilis the perception of the tuning fork through the skull may be lessened or absent (complication with syphilitic disease of the labyrinth), a fact which essentially supports the diagnosis of specific aural affection when other syphilitic symptoms are present," but he does not mention the early appearance of labyrinthine disease during the secondary stage of syphilis.

WATER TREATMENT OF ANGINA PECTORIS.

By CHARLES E. PAGE, M. D.,

BOSTON.

IN an admirable article on Death and Disease on the Stage, in the *North American Review* for August, Dr. Edson refers to "that form of heart disease known to physicians as angina pectoris," often personated by actors for dramatic effect. While, to use a paraphrase, a disease by any other name may sting as much, it doubtless stands less chance of cure than if the diagnosis be correct; and from the delightful effects I have observed from the treatment recommended by the late Professor John Kirk, of Edinburgh, I should be inclined to accept his view as to the true nature of the disease in question, while, on the other hand, the wretched failures attending the routine treatment of angina pectoris as a disease of the heart would seem to indicate pretty clearly to any mind that either the diagnosis or the treatment is far from correct.

It would, of course, never do for an audience to be advised that the hero or heroine in a melodrama dies of a disease so vulgar as stomach cramp, though it might "bring down the house," or clear it out, to give an exhibition of the proper treatment for it—the half-bath, with profuse laving of cold water along the spine! It does, however, occur to me that there may exist here an opportunity for dramatic effect and the winning of a lovely bride by the handsome but impecunious young doctor performing a miraculous cure by seizing a pitcher of ice water and pouring the contents down the heroine's neck!

While I am far from saying that no spasm of the chest (pure English for angina pectoris) ever arises from any cause except the one I have named, nor indeed that the heart itself may not in some instances be the seat of severe pain, I firmly believe that, so far as concerns the great

majority of these attacks, Professor Kirk's position is correct.

"A good many years ago," says Dr. Kirk in his Health Papers, "we ourselves were set down as suffering from what high authority called angina pectoris, and this idea of our illness we find historically retained as giving the proper title to the disease from which we suffered at that long past time. We were believed then to be suffering from some disease of the heart. It is still said to be usually connected with heart disease, but this is a misleading notion. The trouble is a cramp, and that not of the heart, but of the stomach. At first a rather slight pain is felt at the back opposite the stomach. The pain increases and moves round on the right side. If we observe carefully, we find that the heart is going all right. But the pain increases and is soon dreadfully severe. If again we observe carefully, while we find that the heart is still going right, the stomach is cramped and rolled up like a hard ball. It is this stomach cramp that is giving the dreadful pain. Something that rolls the stomach up into that small, hard ball is acting upon it in this cramping way, and we should find out, if possible, what that is and how it may be removed. As a rule, we find the usual treatment, proving that the persons trying to remedy the evil are entirely ignorant of what is going on in the heart of the patient. For instance, applications of the most irritating character are laid over the heart. Digitalis and similar drugs are given—all to quiet the poor heart that is doing its duty perfectly well. The network of nerves in the stomach is in a bad and irritated way, and these so-called remedies are putting that network into a worse and worse state. The angina is being increased to a fury, and the sufferer is getting so ill, as we remember, coming out of bed in anguish and creeping on hands and knees on the floor trying to get relief in any way. It was at this crisis, when ignorant helpers were at their wits' end as to what to do, that Dr. Hunter and his bathman brought a shallow tub into the room. They poured cold water into this and made us sit down in it. They then laved the cold water on the back, and the angina in about two minutes was gone. We felt dreadfully weak from the pain we had endured, but that pain was gone and the stomach, instead of being like a rigid ball, was soft and as it should be. What had really happened? Simply this: the roots of nerves passing from the back to the stomach had been cooled and had relaxed their hold. The cramp was gone, and the pain had gone with it. The bath would be one of about five minutes of cold laving, drying with a kindly rubbing, and finishing with a little olive oil. After one or two such baths the return of the pain will generally cease. So far as we remember, severe mental strain brought on the attack to which I allude."

Where the shallow bath and laving can not be had, the cold compress laid over the back opposite the stomach, and constantly changed, answers a very good purpose, or the patient may be made to lie upon it. I have often given this treatment and have directed it in several cases of long-time sufferers from this disease, and have seldom been disappointed with the results.

It goes without saying that the stomach, of all the

* Politzer. *Text-book*, first edition (German), p. 693.

bodily organs, is the one most constantly and outrageously abused, and therefore the one subject to the most ailments. This alone would not, of course, settle the question, but it is well to bear the fact in mind in this connection, and also to consider the various causes of derangement of the stomach in order that preventive measures may be employed. Aside from the well-known and generally recognized abuses of the stomach, as overeating, bad eating (the use of unwholesome dishes), cascading ice water into the stomach during meals, the employment of alcoholic beverages, etc., one of the most prevalent errors, especially operative with nervous, brainy men and women who seem never to know when they are tired, is that of eating too soon after exhausting work, and of rushing to their work with little or no repose after eating.

Another grand mistake, and a very common one, is that of eating at all when not hungry, simply because it is "meal time"—an act not one whit less stupid than that of replenishing one's fire because he hears his neighbor's coal-hod rattling, regardless of the fact that there is still plenty of black coal on top, and that any addition thereto would be mischievous. Who has not observed instances of persons who go to the table, meal after meal, day in and day out, only to nibble a little of this or that, generally some sort of dainty dish, but never really knowing the pleasure of a "square meal," nor anything approaching it?

In a brief code of *Health Hints*, formulated by the writer some years ago, after many years of earnest study in dietetics, and which he has found small chance to improve during the past ten years of active practice, the first paragraph reads thus: "Never eat when the appetite is even open to suspicion. To eat without hunger is a species of self-abuse inexcusable for sick or well persons. There is no pleasure in such feeding, and it prevents the speedy return of a normal appetite."

ATHETOSIS.

By T. J. MCGILLICUDDY, A. M., M. D.,

SURGEON TO THE NEW YORK MOTHERS' HOME MATERNITY HOSPITAL.

ATHETOSIS, a variety of post-hemiplegic chorea, was so named and first described by Hammond in 1874, but previously noticed by Charcot as an occasional phenomenon in 1853. It is a continuous rhythmical movement of the fingers or toes and a loss of power to retain them in one position. By most writers it is thought to be the result of degenerative changes occurring in the ganglionic masses of gray matter of the corpus striatum or optic thalamus. It is certainly a rare and interesting condition. Dr. William R. Gowers's paper, On Athetosis and Post-hemiplegic Disorders of Movement, in the *Medico-chirurgical Transactions*, London, 1876, points out that the movements never occur in a limb entirely paralyzed; but how could they? Many of his other observations on these conditions were anticipated by Dr. Weir Mitchell. He also says all these cases of disordered movement are much more common and severe in the arm than in the leg, and the hand is the part most seriously affected. The hand is quieter and sometimes the movement

entirely ceases when it is at rest. The disorder is increased by exhaustion, by cold, and by attempts at restraining it, while

FIG. 1

it is quieted by rest and sleep. This condition often results from slight attacks of hemiplegia, and the essential

FIG. 2

element of athetosis is a "slow, remitting spasm," thus differing from the ordinary post-hemiplegic contracture.

Dr. Bernhardt, in Virchow's *Archiv*, Bd. lxvii, Heft 1, and in the *Deutsche medicinische Wochenschrift*, December 2,

FIG. 3.

1876, gives his observations on athetosis, and describes a case in a lad aged fourteen, a son of strong and healthy

FIG. 4.

parents. The hemiplegic condition came on after a convulsion when he was fifteen months old. He was quite

stupid and could not read; his face showed signs of the paralysis. Sensation on the affected side was impaired, and both fingers and toes were implicated in the movement, the toes to the greater extent. The muscles of the leg were noticed to be hypertrophied.

Athetosis is hardly an independent disease, but the result of diseased conditions. M. Comby, before the Société médicale des hôpitaux in 1887, reported a case in a little girl of twenty months, which had continued since the eighth month. It came on after a violent convulsion, due to indigestible solid food, and was limited to the right side, both hand and foot being involved. It is extremely rare in children. Dr. McLaue Hamilton sees no reason for separating athetosis from other disordered movements of hemiplegic origin.

The accompanying photographs show the successive positions of the fingers in a case I saw in October, 1889. The history taken at that time was as follows:

M. S., aged twenty-three years, unmarried. The athetosis, confined to the left hand, has existed since she was five years of age. She remembers nothing about its advent, and has for a number of years been an epileptic, but does not remember how long, as she is not intelligent. The movements are a continuous closing and opening of the hand; the fingers when flexed require a considerable force to extend them. She seems to have not the slightest control over the movements. The little finger generally comes down on the ring finger (Figs. 3 and 4), and the movement of closing seems to start with the middle finger (Fig. 2). Her face shows hemiplegic signs, although her tongue is protruded straight, and she also slightly drags her left leg. She had been treated by electricity without any appreciable benefit. After I had seen her a few times she disappeared, and I learned a year or two afterward that she was dead, but I could not learn the nature of her disease or if an autopsy had been held.

776 MADISON AVENUE.

TENORRHAPHY,

WITH CLINICAL RECORD OF CASES.

By FRED. B. LUND, M.D.,

BOSTON.

(Concluded from page 342.)

Plastic Operations and Grafting.—Before taking up the prognosis and treatment of injuries of the various classes of tendons in detail, a word ought to be said about what can be done in those cases where a portion of tendon has been removed by the accident, leaving a gap which the surgeon must strive to fill up with tendon tissue, if possible; or cases in which the same untoward result is produced by the necessity of refreshing the ends in secondary suture. One surgeon (Gluck*) claims to have even filled up with new tendon tissue a gap caused by suppurating and sloughing. Where a gap exists, no matter how slight, in the continuity, we should never sew the ends together, under the impression that a slight shortening will do no harm. Any shortening, however slight, of a flexor will be sure to prevent complete extension of a finger, and *vice versa*. It

* *Deutsche med. Wochenschrift*, 1884, No. 48.

is as important to restore the normal length as the continuity of a tendon. We must aim, then, in some way to fill up the gap between the ends, if possible, with tendon tissue—at any rate, with cicatricial tissue, which shall firmly unite the ends, and may in some cases supply the place of tendon tissue.

For the attainment of these objects methods have been devised which may be divided into four classes:

1. Suture of the ends at a distance (the suture being merely to hold the ends in place), and allowing each end to become adherent to the cutaneous cicatrix. When the skin is freely movable, as over the back of the hand, a portion of skin and fascia may be made to supply the place of tendon with excellent result.*

2. A plastic operation, by which a piece of sufficient length may be split out and turned down from one end, as shown in the diagram. Hüter and Czerny have reported

Fig. 5.

successful results from this operation. Necrosis of the flap is not to be feared, although it might seem inevitable from the almost complete isolation from its source of blood supply. If necrosis should occur and our wound were aseptic, the dead tendon might serve as a bridge for the growth of new tendon tissue (like Gluck's bundles of catgut).

3. The method recommended by Gluck of interposing foreign bodies, such as bundles of fine aseptic silk or catgut, to act as a bridge or guide for the growth of new tendon tissue. He reports a successful case in which he thus supplied a gap in the extensor indicis and extensor tendon of the middle finger, extending from the metacarpo-phalangeal joint to the wrist. In the hands of other surgeons, however, the simple suture of the tendons at a distance, so that perhaps two or three threads of catgut ran between the ends, has given better results. Bulky foreign bodies may be rejected even from an aseptic wound, unless a very abundant blood supply affords the means for their encapsulation. In general, it is safer not to leave a large bundle of silk or catgut in a wound. If any foreign body is to be introduced to supply the gap, it would seem a rational procedure to employ tissue of the same character as that to be replaced—namely, tendon. This leads us to the consideration of the fourth method.

4. Implantation of a piece of tendon taken from an animal—grafting.

This method has the disadvantage of requiring a double tendon suture—one for each end of the tendon introduced—and has been rarely done. Successful cases have been reported by Tillaux and Lefort, and Peyrot† reports a case of transplantation of a piece of tendon from a dog, with partial restoration of function. This operation, though inferior to the plastic operation described above, seems to the writer preferable to the introduction of foreign bodies—

silk, catgut, etc. It would seem best in doing this operation to place the sutures in the divided tendon, and also in the piece to be cut out from the heel cord of the dog or other animal before cutting it out, so that when excised it may be immediately placed in position and the sutures tied. We thus avoid unnecessary manipulation of the excised piece, which might result in necrosis. In this manner the writer supplied a defect of two months' standing in the tendo Achillis of a dog, made by excision of about an inch of the tendon. The gap was supplied by implantation of a piece from the heel cord of a rabbit, which was sewed in place with silk in the manner recommended above. The wound healed by first intention, and the tendon united, with perfect restoration of contour and function.

5. Implantation of the peripheral end in a neighboring tendon, thus transferring a part of the action of the muscle belonging to the latter to the former. This may also be adopted in cases where we are unable to find the central end. Although this latter predicament is one which ought to occur very rarely, there are circumstances in which this transference of action may give very good result, as, for instance, the suture of the peripheral end of a severed flexor profundus to the sublimis in the palm, thus enabling the patient to flex the finger. By this means also we can employ the flexor carpi radialis or ulnaris for the purpose of flexing the fingers. Where the extensor of one finger is sewed to that of another, the extension of these fingers independently of each other becomes, of course, impossible. This, however, is a comparatively slight annoyance. The extension of the fore and little fingers may be safely intrusted to their proper extensors, while their portions of the common extensor are employed to take the place of the injured extensors of the other fingers. (Cf. case reported by Wölfler.*) After this brief discussion of the methods of supplying defects in tendon tissue, we come to the discussion of the suture of the different classes of tendons in detail.

Prognosis and Treatment of Injuries to Special Tendons, illustrated by Cases of Tendon Suture done at the Massachusetts General Hospital within the Last Five Years.†—Before beginning this discussion the author must acknowledge his indebtedness to the masterly article of Wolter on *Die funktionelle Prognose der Sehennaht* for the classification of these injuries on an anatomical basis, and to the records of the Massachusetts General Hospital for the histories of most of the cases. The cases presented were all seen by the writer, some of them three or four years after the operation, but for the description of the original injury he had in most cases to depend on the hospital record.

We will first consider the extensors ossis metacarpi, and primi and secundi internodii pollicis.

These tendons offer most favorable anatomical conditions for suture. They run in loose connective-tissue sheaths, and the skin over them is so freely movable that adhesion to it is harmless. Over the metacarpal bone of the thumb the extensors primi and secundi internodii are so firmly united to the periosteum by fibrous bands that retrac-

† Reported by the kind permission of the visiting staff

tion is possible only to the extent of about one centimetre, as in shown both in life and by experiments on the cadaver. Over the wrist joint, however, these tendons may retract from six centimetres (Czerny) to ten centimetres (Duplay).

Wolter reports four successful cases of suture of one or both of the extensors of the phalanges of the thumb, in all of which perfect restoration of function was attained. The very short time of recovery in two of his cases (twenty days) he ascribes to the method of treatment by the "moist blood clot."

The writer reports two cases:

CASE I.—(History from hospital record.) P. S., laborer, aged thirty-one years. Transverse cut of right wrist two inches and a half long across the anatomical snuff-box, made by broken glass. Radial artery and tendons of extensor ossis metacarpi and primi internodii pollicis cut squarely across. Radial tied with silk. Longitudinal incision half an inch long over the tendons made to find the central ends, which had retracted. Silk suture of tendons and skin. No drainage. First dressing three days later.

One month later seen by the writer. Scars of wounds as described. Extension of thumb normal. No adhesion of tendons to skin.

CASE II.—J. P., aged thirty-one years, laborer. Transverse cut of right wrist across anatomical snuff-box, made by a razor. Extensors ossis metacarpi, primi and secundi internodii pollicis divided. Retracted ends found by a longitudinal incision about an inch long over the tendon. Suture with silk. No drainage. Hand dressed in a position of extreme extension and held so by a splint with a roller bandage placed on the back of the wrist directly over the wound as shown in Fig. 6. First dressing

FIG. 6.

three days later. No pain; apparently first intention. Considerable oedema of back of hand, probably due to pressure of the roller bandage. Fifth day: Has complained of considerable pain. Marked oedema and tenderness about wound. Suppuration in the angle between the two incisions, slight and limited to this position. Roller removed from wrist; moist corrosive dressing daily. On sixth day the small opening at the angle of the wound was enlarged with scissors, permitting free escape of pus. After granulating for two weeks the wound healed.

Two months later the patient had perfect restoration of function, the skin moving only slightly with the tendons. It is an interesting point in this case that perfect restoration of function took place in spite of suppuration. This resulted merely in adhesion to the cutaneous cicatrix, which in these cases does not interfere with function. Duplay* reports a similar case, which was successful in spite of suppuration. Heuch reports a case of an operation in which the cutaneous cicatrix was made

to fill a gap in the tendon of the secundi internodii pollicis, with perfect restoration of function.

Case II also illustrates well the point made by Schüssler that the hand should not be dressed in a position of too extreme flexion or extension, owing to danger of interfering with the circulation and therefore with the healing of the wound. In the writer's opinion, the suppuration in this case was due to the pressure of the roller bandage directly over the angle of the flaps, causing necrosis.

Suture of the Extensor Communis Digitorum and Extensor Indicis over the Back of the Hand.—As we have noted above, suture of the extensors over the back of the hand has an especially favorable prognosis, and it is also in this region that plastic operations, etc., upon tendons are done with the greatest hope of success. The skin is here freely movable, and the tendons run in loose connective-tissue sheaths, formed by a reduplication of the deep fascia, these sheaths being themselves freely movable, on the one hand, under the skin, and on the other over the metacarpal bones. This deep fascia can, in thin persons, be seen to move *under* the skin and not *with* it, as Wolter has noted. The connection of the tendons with the deep fascia which forms their sheath is so intimate that in cases where a short transverse cut divides the tendon alone the ends are held in apposition. When the fascia is divided with the tendon by a cut, say four centimetres long, the central end will retract only about two centimetres. The fascia here holds the tendon so firmly that in cases of suture we have rarely to apprehend trouble from tension on our sutures. There is hardly an unfavorable accident to apprehend if care be taken in the treatment of these cases, except, of course, where there is a simultaneous fracture of a metacarpal, when there is danger of adhesion of the tendon to the callus. This may, however, be in most cases arrested by persistent massage and exercise of the part.

Moorgue,* Tillaux,† and Notta have reported cases where the tendons healed without adhesion to the cutaneous cicatrix.

Successful secondary suture of these tendons was done in preantiseptic days by M. A. Pettit,‡ Sedillot,§ and Velpeau.

Anger|| successfully united the separated ends by a cutaneous cicatrix in a case of secondary suture. Moorgue and Pollaillon^ have reported cases in which the tendons did not adhere to the skin in spite of suppuration. In the cases of Pettit and Sedillot, referred to above, the suture (secondary) was successful in spite of suppuration. Kottman had a good result in a case complicated by fracture of two metacarpals. Gluck's famous case of replacement of

tendon by aseptic catgut from the wrist to the metacarpophalangeal joint was done upon the extensors over the back of the hand; and the cases might be multiplied.

The following cases of suture of these tendons came under the writer's observation. Two of them are of interest as being complicated with fracture of the metacarpals and crushing of the soft parts (Cases V and VI):

CASE III.—T. M., laborer. Extensors of middle, ring, and little fingers of left hand divided by a cut with broken glass over the back of the hand. Suture with silk. Quill drainage. Passive motion in four weeks. Seen by writer after six months. Function in all the fingers normal. Tendons move independently of skin except that of the little finger, where the cicatrix is slightly adherent. Patient says that three small pieces of glass were removed from the wound at this point.

CASE IV.—E. F., carpenter, aged twenty-seven years. Extensor communis of middle finger and extensor indicis cut by a glass globe falling on the back of the hand. Opening on the back of the hand enlarged. Ends of tendons united by silk sutures. Wound sutured without drainage. Seen by writer after four years. Complete restoration of function. Independent extension of fingers. Skin adherent to cicatrix. Patient says he was able to work six weeks after the accident.

The above-given cases are examples of the usual result in these cases. We may note that one was treated with and the other without drainage.

CASE V.—J. K., aged thirty years, printer. Lacerated and contused wound of back of right hand caused by hand being caught in a printing press. Wound extends from near distal end of first metacarpal to near proximal end of fifth. Compound fractures of all the metacarpals along this line. Extensor tendons of index and ring fingers divided. Crush of soft parts of ball of thumb. Mass of ragged muscle removed from adductor side of thumb. Tendons approximated with silk sutures. Skin flaps drawn loosely together with silk. Drainage-tube. Moist corrosive dressing. Stitches and tube removed after six days, no suppuration having taken place. Two weeks later the patient was discharged, to be treated in the out-patient department. Seen by writer after two years. Flexion of fore, middle, and ring fingers almost normal. Extension normal. Hand is strong and patient is perfectly able to do the work of a printer, a trade requiring accurate and independent movement of the fingers.

CASE VI.—J. S., aged fifteen years, press feeder. Ragged tear across dorsum of left hand, caused by its being caught in a printing press, about four inches long. Compound fracture of second and third metacarpals. Carpo metacarpal joint opened. Soft parts badly lacerated. Two superficial cuts over palm of hand. Hand considerably swollen. Tendon of common extensor of index finger severed. Wound thoroughly irrigated with biniodide solution. Tendon sutured with fine silk. Small rubber drain into joint. Suture of wound. Splint and dry dressing.

Next day considerable pain. Temperature, 102°. Redressed. Hand found puffy and palmar stitches tense. Tense stitches loosened and back of hand scored, allowing escape of blood. Pain much relieved.

Five days later, tube out.

Fifteen days later, healed except granulations along dorsum. Slight motion in fingers. Discharged to out-patient department.

Seen by writer one year after injury. Large callus over proximal end of first and second metacarpals. Movements of

fingers normal, except that forefinger can not be completely extended, but droops a little. Patient does his work as a press feeder and is not inconvenienced by the droop.

Cases V and VI are of especial interest as showing what can be done where we have to deal with fracture of bones and laceration of soft parts, and emphasize the fact that tendons should be sutured in cases of the most complicated injury, where the wound has to be treated as an open one. In Case V there was no adhesion between the tendons and the bone callus, and in Case VI it was but slight.

These cases may well be contrasted with a case seen by the writer of section of the extensor tendons of the index finger by a cut with glass. The patient was a painter. The ends of the tendons could be felt adherent to the cicatrix and separated about two centimetres. Flexion of the finger was normal, but extension only about two thirds normal. The finger hung down so as to constantly interfere with the patient's use of the hand. This is a very typical result of an untreated section of an extensor. Secondary suture would probably insure perfect restoration of function.

Suture of Extensor Tendons over the Wrist.—The prognosis is not as good in these cases as in those last discussed for two reasons: First, that the tendons here run in a stiff-walled synovial canal, and, second, because they lie so close together that adhesions are apt to result. The tendons here move fully four centimetres in passing from complete flexion to complete extension, so that adhesion between the tendon and any immovable structure will have a very bad effect. Wolter reports a case, however, in which he secured perfect restoration of function. The moist blood-clot method was employed. There was no reaction, the dressing was changed in three weeks, and passive motion begun in four. The tendons sutured were the extensors ossis metacarpi and primi internodii pollicis, extensor carpi radialis longior and brevior, extensor secundi internodii pollicis, and extensor indicis.

Suture of Extensors over the Metacarpophalangeal Joint.—The prognosis is especially favorable. The tendon is so firmly attached to the joint capsule that unless the joint be opened retraction can not take place. In case the joint is opened retraction takes place only to the width of the wound. Even in this latter event, however, the ends of the tendon can be brought into apposition by strongly extending the fingers. Without the opening of the joint the suture is extremely simple, and if the joint be opened it is not a serious complication. In a case complicated in this manner, Wolter employed the moist blood-clot method and obtained a perfect result. If suppuration takes place in the joint cavity, adhesion and stiffness of the joint results, as happened in one of Wolter's cases.

Suture of Extensors over the Phalanges and Interphalangeal Joints.—Here the tendons, increased in width by accretions from the interossei and lumbricales, glide freely under the skin and over the periosteum. Over the phalanges the skin is very slightly movable, over the interphalangeal joints it is necessarily looser. In flexors, even the skin over the joints is tightly applied. The skin is firmly united to the sheath of the tendon and the capsules

of the joints. It is to be noted that here the tendons themselves complete the capsules of the joint, so that section of the tendon implies opening the joint. Flexion and extension are possible only provided the tendon can move freely under the skin and over the periosteum, so that adhesions to these structures prevent a functional success. The tendons move only about half a centimetre in passing from flexion to extension, so that very slight limitation of motion will have great effect upon function. If these tendons are not sutured, active extension of the distal phalanges becomes impossible and flexion more limited as time progresses (Segond,* Busch †). If the tendon be sutured and the finger be kept for a long time in a position of extension, good results may be obtained, especially in suture opposite the first phalanx. With crushing of the soft parts and bones, however, we are apt to get adhesions which interfere greatly with the recovery of function. Any shortening of the tendons (refreshing the ends) is fatal to success. Wolter reports three cases. In one of them the bone was uninjured and partial recovery of function resulted. In two of the cases, in which the bone was broken, the result was poor.

CASE VII.—D. M., aged about thirty, carpenter. Extensor of middle finger severed by a knife-cut over the second phalanx. Sutured with silk. Suture of skin wound. Finger dressed with phalanges extended. Slight suppuration followed and the suture was extended. Four weeks later the wound was healed. The finger can not be completely extended and only partial flexion is possible. Functional result poor.

Suture of Flexor Tendons over the Wrist.—We have here to deal with two classes of tendons which may be called the superficial and the deep. The superficial set run in loose connective-tissue sheaths outside the annular ligament, and include the flexor carpi radialis, palmaris longus, and flexor carpi ulnaris; their sheaths are formed by a reduplication of the superficial fascia, from which the flexor carpi ulnaris has a partial origin. The deep set include the flexor sublimis and profundus digitorum and flexor longus pollicis, and run under the annular ligament close together in a common synovial canal. The superficial tendons glide only about a centimetre and three quarters in performing their function, and when severed retract about the same distance. The flexors of the fingers, however, have a motion of about two centimetres and a half, and retract the same distance. The superficial set are provided with an efficient aid to repair in their vascular sheaths of connective tissue, and may form adhesions to the skin without greatly affecting their functions; the deep set have no vascular sheath and lie so closely packed that they are in great danger of forming adhesions to each other and to the walls of their synovial canal, both of which are extremely prejudicial to function. The prognosis is therefore far better in injuries to the superficial than the deep set of tendons. The prognosis is also impaired by the fact that in all deep wounds of the wrist the median or ulnar nerve is apt to be divided. Suture of these nerves, however, has given excel-

lent results. Wolter reports a case of suture of the palmaris longus, flexor carpi radialis, and flexor carpi ulnaris, in which recovery of function was almost complete in seven weeks; a case of suture of all the tendons on the front of the wrist, except the flexor profundus, in which one half the normal mobility was recovered (the median and ulnar nerves were also sutured); a case of primary suture of the ulnar nerve and the tendons of the palmaris longus and flexor carpi ulnaris, followed eleven weeks later by suture of the tendons of the sublimis, with only partial recovery of function; two cases of primary suture of the third and fourth tendons of the sublimis—one treated by drainage and the other by moist blood clot. In the latter case complete recovery of function resulted in four weeks; in the former it was almost complete in forty-four days. It is in just these cases where the tendons run in long synovial canals that Wolter considers the treatment by moist blood clot to be of the greatest importance. The following cases are none of them uncomplicated suture of these tendons, but are of interest from the extent of the complications.

CASE VIII.—J. K., dry-goods clerk. Secondary suture of median nerve, tendon of flexor carpi ulnaris and ulnar nerve, with fine silk, by means of two longitudinal incisions of about two inches—one over the median and the other over the ulnar nerve. The section of the ulnar nerve had resulted in considerable atrophy of the interossei, and in the hand being held in the "claw" position. Sensation had completely returned in three weeks. Four months later, under treatment by massage and electricity, he had obtained complete flexion and almost complete extension of the hand and fingers. One year later he is perfectly able to attend to his business, and is not troubled at all by his hand. An excellent result of nerve suture.

CASE IX.—J. H. McG., aged eighteen, mechanic. Left wrist struck by the blade of a Sturtevant blower. All the tendons on the front of the wrist divided except the deep flexor of the little finger. Radial artery and median nerve divided. Compound fracture of radius and ulna. Ulnar artery and nerve not injured. Compound fracture of last phalanx of thumb. Hand hanging by the skin and tendons of the back of the wrist. Under ether, and with careful antiseptic precautions, Dr. Conant sutured all the severed tendons and the median nerve. Terminal phalanx of thumb amputated and wound closed without drainage. Hand dressed in a position of flexion of the wrist and fingers. Wound healed by first intention throughout. One month later sensation had returned except on the radial side of the forefinger. Slight motion of all the fingers possible, but apparently due to the action of the interossei in great part. Tendons at wrist, however, move slightly, and the adherent skin to move with them. Union of bones firm. Considerable callus. Six months after the injury the sensation was perfect, the movements of the thumb good, and patient can approximate the thumb and forefinger. Flexion and extension of the fingers about one half normal. Tendons move more freely under the skin.

The above result shows what it is possible to do in one of the severest types of injury which is ever presented to the surgeon. We had here a suture in an unfavorable region, and with every possible untoward complication, fracture of bones, laceration of soft parts, and division of nerves. The treatment was without drainage, and the fact that healing took place by first intention was of the greatest importance to the result.

* Segond. *Progrès méd.*, 3 juillet 1880.

† Busch. *Centralblatt für Chirurgie*, 1881, No. 1.

CASE X.—M. F., bank cashier, aged sixty-five. Right wrist injured by broken window glass in a railway accident. Ulnar artery wounded and an attempt made to tie it before he was brought to the hospital, which was unsuccessful. Brought to the hospital five hours later. Lacerated wound of right wrist (ulnar half) about an inch and a half long, just above the styloid process of ulna. Ulnar nerve, flexor carpi ulnaris, and the three inner tendons of the flexor sublimis divided. Proximal ends retracted. Under careful antiseptic precautions an incision three inches long was made in the middle line of the arm, parallel to the tendons. The ends of the tendons and nerve were found by careful dissection, brought into good position, and sewed with catgut. A rubber drainage-tube was inserted and the skin sewed with silk. Two days later the drainage-tube was removed. One week later there was evidence that one of the tendons was sloughing. Fair sensation present in the fingers supplied by the ulnar nerve. Discharged to the out-patient department. Two months later the arm had to be incised to permit the escape of pus and sloughing tendon. Exactly how much tendon sloughed could not be ascertained.

Seen by writer after fifteen months. Wrist held in the position of palmar flexion and fixed there by adhesions. Fingers held in position of extension of first phalanx, and slight flexion of the other two. No motion at wrist or at interphalangeal joints. Slight motion at metacarpophalangeal joints of fore and middle fingers. Good motion of the thumb. Skin of fingers bluish and shiny. No sensation over area supplied by ulnar nerve. Atrophy of interossei.

The above-given case is a good illustration of the results which follow suppurative along the course of the deep tendons on the front of the wrist. In this region we can not hope, as over the back of the hand, for good results in spite of suppuration. Necrosis and sloughing of the tendons are almost inevitable, on account of the synovial sheaths furnishing such an easy road for infection. Adhesions will result where we are fortunate enough to escape sloughing. The wrist joint in this case is probably ankylized; at any rate, it is so held by the agglutination of the tendons under the annular ligament that the same condition results. Owing to the unfavorable situation, the hope of success of a secondary operation to dissect the tendons free from their adhesions would be very slight. The evidence of ulnar paralysis shows that the suture of the ulnar nerve was ineffectual. A plastic or other operation to restore the gap in the nerve or tendon in a man sixty-five years of age would give small hopes of success. Whether the drainage-tube was the offending agent in this case it is difficult to say. At any rate, the drainage-tube offers a possible route for infection, and necessitates frequent dressings, both of which are prejudicial to our results. There is good reason to think that the handling which the wound received at the scene of accident, in the unsuccessful attempt to tie the ulnar artery, may not have helped toward an aseptic result.

Suture of Tendons in the Palm.—In the palm of the hand the conditions for suture are far more favorable than at the wrist. The pairs of tendons run separate from each other in their sheath under the palmar fascia. They are connected with each other and with their sheath by a layer of loose connective tissue. The sublimis here retracts about three centimetres, the profundus about two centime-

tres. If the tendons here be left unsutured, the affected fingers can not be flexed at the interphalangeal joints, and very slightly at the metacarpophalangeal (interossei and lumbricales). Adhesion of the tendon cicatrix to the skin, which is here held by the firm palmar fascia, is extremely prejudicial to the result. It is to be avoided by securing first intention and by careful and thorough passive motion, also by making our cutaneous incision not over but parallel to the tendon, as suggested by Sedillot and emphasized by Witzel. A comparison of Cases XI and XII will show well the difference which suppuration makes in the prognosis. Wolter reports a case of secondary suture in this situation, with a fair result, somewhat affected, however, by adhesion to the skin.

CASE XI.—J. J. S., aged twenty-six years, brass founder. All the flexors of the fingers of the left hand in the palm cut by the pointed tool of a brass-turning lathe. Transverse wound of palm. Ends of all the tendons in the palm found by Dr. Porter, except the central end of the deep flexor of the little finger, and marked by sutures. Vessels tied with catgut. Tendons either sutured or the loose ends of the marking sutures tied up snug. Short tube in palm. Silk skin sutures. Lister gauze and absorbent dressing. First dressing three days later. First intention. In three weeks slight motion of fingers. Passive motion not begun for five weeks.

Seen by writer three years later. Perfect and independent flexion and extension of the fingers. Cicatrix in palm a mere line. No adhesion of tendons to cicatrix. Patient went to work six months after the accident, and has ever since been perfectly able to do his work as a brass finisher. Result perfect.

CASE XII.—W. W., aged about twenty-five years, railroad. Cut by falling on a piece of broken glass. Transverse cut of right palm, near ulnar side, about an inch and a half long. Unable to move little and ring fingers. Under ether, superficial and deep flexors of ring and little fingers found to be severed. A longitudinal incision, about four inches long, was necessary in order to find the proximal ends. Sewed with silk by quilt suture. Ten days later the wound looked well, and the patient was discharged, having slight motion of the affected fingers.

When the patient reported to the out-patient department a small suppurative sinus was found in the angle of the wounds. After some weeks a small piece of iodoform gauze was extruded and the suppuration stopped. Six months later the fingers were held in a position of partial flexion. Active motion possible only through an arc of about 20°.

Two causes evidently contributed to secure this poor result—first, the long suppuration; second, the long incision required to find the retracted ends.

CASE XIII.—E. B., aged thirty-three years, shoemaker. Short incised wound in palm of right hand, one day old, made by broken glass. Superficial and deep flexors of ring finger found to be divided. The transverse incision was slightly enlarged, and the retracted central ends easily found by a short longitudinal incision, the old blood clot serving as a guide. Ends of tendon united by catgut sutures. Palmar arch tied. Wound closed by interrupted silk sutures. First dressing in five days. First intention.

Seen by writer after a year. Extension perfect. Flexion almost complete, but finger can not be quite doubled into palm. Patient says his power of flexion is still improving. Functional result good.

Suture of the Flexors over the Fingers.—Here each tendon runs in a separate synovial canal, with firm, unyielding walls. Retraction is, however, slight, because the tendons are bound to the joints by fibrous bands—the vincula tendinum. Retraction is greatest over the first phalanx, where it may amount to one or two centimetres. Owing to the fact that the sublimis is inserted into the second phalanx, it can hardly retract at all when divided there. The profundus is also so firmly adherent that retraction of only about one centimetre takes place. Over the second phalanx the tendon sheath fits more closely than over the first, so that here there is more danger of adhesions. According to Volkmann,* when these tendons are severed, whether they are sutured or not, the function is almost invariably destroyed by adhesion to the sheath or the bone. Nevertheless, Wolter reports three cases of suture opposite the first phalanx, with complete recovery of function. In three cases of suture opposite the second phalanx he secured active flexion of the second phalanx in only one case, and of the terminal phalanx in none. He reports, however, a very interesting case of secondary suture of the flexors opposite the second phalanx of the right index finger in a pianist. Active flexion of the terminal phalanx was before the operation impossible. The injury was a cut with broken glass three months before. Dr. Cordua operated, finding retraction of about one centimetre. The ends were dissected free from a mass of adhesions, and two catgut sutures employed for each tendon. Blood clot. First dressing in three weeks. The final result was a complete restoration of the power of flexion of the index finger.

Madelung† also reports a case of suture opposite the second phalanx where flexion of the terminal phalanx was restored. He employed his own method of making a separate incision to find the retracted end, which we have described above. For obvious reasons, it is the method *par excellence* for the flexors opposite the phalanges, as it involves the least wounding of the sheath and consequent danger of adhesion.

CASE XIV.—Wife, aged twenty-four years. Both flexors of forefinger of right hand cut by a bread knife opposite the first phalanx. Flexion of two other phalanges impossible. Cocaine. Central ends found retracted about one centimetre by a longitudinal incision. Silk suture. Primary union. At fourteen days slight flexion of the terminal phalanges was possible. The finger was fully and violently extended by an incautious dresser, causing great pain to the patient, undoubtedly rupturing the adhesions which held the ends. No active flexion of the terminal phalanx resulted.

This case illustrates well the result of unskilled handling of these cases, but throws no light on the prognosis of a properly treated case. The cases of Cordua and Madelung should lead us, however, to attempt suture in these cases, for they prove that, with the greatest care and in favorable cases, good results may be obtained.

Suture of Tendons over the Dorsum of the Foot.—Here, as over the back of the hand, we find every condition favor-

able for suture. Connective tissue forms the sheaths, and the skin is movable. Retraction of four centimetres is possible; beyond this it is prevented by the bands of connective tissue which unite the tendons to the skin and deeper parts. Wolter reports two cases—one of suture of the tibialis anticus and one of the extensor longus hallucis, both with good result.

CASE XV.—R. E., aged eleven years. Transverse lacerated wound of anterior part of left leg just above the malleoli, made by a mowing machine. Tendons of tibialis anticus, extensor longus pollicis, extensor communis digitorum, and peroneus tertius severed and ends somewhat separated. Tendons united with catgut sutures and wound closed with interrupted silk. First intention. Two months later extension of the ankle and of all the toes except the great toe was normal. The latter could not be extended. Four months later the great toe could be partially extended, and the patient says it is still improving.

The case is interesting as illustrating the fact that we can not pronounce upon these cases within a month or two after the operation; but that a result which seemed poor at first may present a totally different aspect in a year or two.

Suture of the Tendons of the Quadriceps Femoris and Ligamentum Patellæ.—Rupture of these tendons, like fracture of the patella, is usually subcutaneous, and the result of muscular action. The question of suture is an interesting one upon which there is not enough evidence to form a definite conclusion. So far surgeons have manifested marked reluctance to make these injuries compound, considering that the dangers of this method offset its obvious advantages of shorter time of treatment and more perfect apposition. We can not help thinking that the suture of these tendons will in time come to be recognized as the regular surgical procedure. Certainly it is less dangerous than wiring the patella, which is a procedure now often adopted in simple fracture.

Suture of the Tendo Achillis.—Whether in any given case of section of the tendo Achillis we should undertake suture will depend upon whether it has been severed within three centimetres of the calcaneum (in the adult) or above that point. From the lower end of the tendon as far as this point are given off strong fibrous bands running to the upper anterior surface of the calcaneum. In section of the lower end of the tendon, these will permit a retraction of more than one centimetre—a distance so slight that the ends can be brought into apposition by strong plantar flexion of the foot, so that suture will be superfluous (Mitchell).* In section of the tendon above this point the central end will retract four centimetres, and sutures should be employed to hold it in place. Unless this be sutured, the separated ends become fixed and adherent; the patient can not flex the foot, and must walk with lameness and difficulty. Syme,† Debove,‡ and Annandale* have reported good results from secondary suture in these cases. Wolter

Extensor over foot.....	XV	"	Catgut.	"	"	Present.	Good.

also reports a case of secondary suture of this tendon which was successful.

Table of Cases reported in this Paper.—In order to show more plainly still the good prognosis which attends tendon sutures in general, the writer appends the above tabular view of the cases which have been discussed above in detail. A good result in eleven out of fifteen cases indiscriminately chosen certainly argues well for the operation of tenorrhaphy, and stigmatizes its non-performance in any cases where tendons are divided and the member be not absolutely crushed to an extent that amputation is the only alternative.

Besides those points which have been sufficiently emphasized in what precedes, this table brings out the following points of interest:

In our series of fifteen cases silk was employed in twelve and catgut in three. Drainage was employed in five cases. In eleven cases the wounds healed aseptically, in four they suppurated.

In five cases the normal function was restored; in four cases almost normal (good) function was restored; making nine cases in which the results were excellent—in one (Case II, an extensor suture), in spite of suppuration; in two others (Cases V and VIII), in spite of complications.

Of the four cases which suppurated, the result was poor in three.

Of the five complicated cases the result was good in two, partial in two, and poor in one. Besides the nine cases in which the result was excellent, we have, then, two in which partial success was attained, making in all eleven successful cases.

122 MARLBOROUGH STREET.

The New York Hospital Training School for Nurses.—

A reception was given by the graduating class on Saturday evening, September 30th. The class consisted of Miss Agnes L. Witbeck, Miss Annie B. Duncan, Miss Mary M. Goodrich, Miss Marie A. Vreeland, Miss Christine Wetmore, Miss Rose A. McKay, Miss Elizabeth D. Holt, Miss Florence M. Linton, Miss Hessie J. Dickson, Miss Sarah L. Gladwin, and Miss Edith S. Saunders.

The Society of Medical Jurisprudence.—A paper entitled Legal Dogmatism on the Subject of Insanity is announced to be read at the next meeting, on Monday evening, the 9th inst., by J. Hampden Dougherty, Esq.

CELLULAR THERAPY:

ITS PRACTICAL ADAPTATION
IN THE RATIONAL TREATMENT OF DISEASE.*

By JOHN AULDE, M. D.,
PHILADELPHIA.

THE general practitioner as well as the specialist in this last decade of the nineteenth century, with all the knowledge that science and skill can command, from the nature of his environment, is still handicapped in his efforts to control and modify disease. And yet, with the wonderful achievements of the recent past in demonstrating the realities which are responsible for the spread of illness, many of the remedial measures of to-day differ but slightly from those in vogue a quarter of a century or more ago. Admitting as true all the well-grounded observations which science has placed at our command relating to the microbic origin or causation of disease, except in the domain of surgery, but little has been accomplished in the matter of arresting or mitigating the mephitic influence of these micro-organisms and their products when once fairly entrenched within the system.

The physician of to-day is confronted by a condition, not a theory; at most critical periods he finds his therapeutic resources inadequate and unsatisfactory, and lapses into blind empiricism, because, forsooth, his study of remedial agents has been conducted through a series of labyrinthine channels or bypaths which shed no light upon the natural method of investigation. Just as a squad of Western horsemen, galloping along the banks of a treacherous mountain stream to escape the dangers of a rushing torrent at their heels, have no conception of the auriferous particles mingled with sand and dirt thrown in their faces by the frightened and fleeing steeds, so the ordinary physician appears to be utterly oblivious to the sterling worth of physiological truths brought to his attention every day, and at times in sufficient number to almost blind him.

The physician is naturally led away from the proper study of remedies by reason of his disposition to study and seek *results* rather than to critically inquire into *methods by which results are obtained*; hence nearly all general practitioners have erected for themselves a medical super-

* Read before the Mississippi Valley Medical Association at its nineteenth annual meeting.

structure which often rests upon an exceedingly unstable foundation. The thorough clinical study of any well-known representative drug whose physiological action has been determined would not only be a blessing to humanity, but would prove a revelation to the observer and would go very far toward re-establishing confidence in therapeutics as a science. It is my purpose, therefore, in the following remarks to direct your attention to the therapeutics of the cell, or *cellular therapy*, briefly pointing out its practical adaptation in the rational treatment of disease.

Disease, as seen by the physician, is either organic or functional. In nearly all functional cases symptomatic treatment will be sufficient to relieve; but, in order to advise symptomatic treatment to advantage, we must have a tolerably correct knowledge of the physiological action of the remedies employed. What might be termed heroic treatment will apparently succeed in many instances, but too often these heroic methods, while they smother the ailment for which they are given, leave the condition of the patient worse than at the beginning. The surgeons have learned that opium to relieve pain may prove most unfortunate, but physicians seem slow to appreciate this important and significant truth.

When speaking of the need for understanding the physiological action of medicines, I do not mean the gross symptoms or the toxic symptoms, but rather the manner and order in which the various symptoms are produced; the incidental effects, both mental and physical, together with the microscopic effects as shown by an autopsy. In addition to this, however, must be considered the unseen effects, both during life and after death; but for the present it will be sufficient to confine the discussion to effects that will permit of physical demonstration or those which properly come within the scope of clinical medicine. Our knowledge of disease processes and our perception of the remedial value of therapeutic agents are practically determined when we have demonstrated the metabolic changes produced in the living cell, but there are influences above and beyond this which finite minds are unable to comprehend or calculate. It is but a few years since Edison astonished the civilized world by sending two telegraphic messages over the same wire at the same time, but his next achievement was even more wonderful—namely, that of sending two messages over the same wire in each direction at the same time; and the end is not yet, as we learn that the next step will be sextuplex and octoplex systems taking the place of duplex and quadruplex. Dolbear maintains that seventy-two messages can be sent over the same wire—thirty-six in each direction. Notwithstanding these marvelous results, they are as nothing compared with the possibilities of the human nervous system—possibilities which we have no ability to estimate or compute.

Dr. Hodge has recently made some interesting experiments with a view to determine the effects of exhaustion and stimulation upon the nervous system of bees, and it now remains for the experimental physiologist to tell us the influence which disease products and therapeutic agents exert upon the nervous system of the human economy, meaning by this the effect upon the nerve cell. In

the case of many familiar and popular remedies, while we know the characteristic changes which they produce in the cell structure and upon the tissues as a whole, our knowledge is practically limited to these physical facts, and the effect upon the nerve supply of the tissues involved continues as profound a secret as if hidden in the pages of a sealed book. Doubtless, when science shall have reached this period, the mortality rates from disease will be materially reduced, and that from medication entirely disappear. Evidently the signs of the times point to a revolution in methods of treatment, although we must expect opposition from agitators until the dawn of the millennial period.

We know that external as well as internal impressions are conducted along the nerve paths with incredible speed, not one, but many, and still we are unable to trace the effects of this "action" by any known process or method of investigation. Nor can we demonstrate the molecular changes taking place in the wire after the transmission of the electric current, impulse, force, manifestation, or whatever we are pleased to term it. In the case of disease, for example, we may study the subjective and objective manifestations of a concealed poison upon the nervous system, and, from our knowledge of physiological action, may introduce a remedy which, for the time, controls the abnormal condition present; but this is a method superficial in the extreme, since it takes no account of the original cause, nor of the actual changes produced in the nerve supply by the derangement of function.

In the successful treatment of typhoid fever by cold baths—without the employment of drugs—we are furnished with a modern instance of the absolute helplessness of the physician were human life solely dependent upon his theoretical confidence in medicine. In view of the fact that this hitherto fatal malady may be brought to a successful termination independent of those skilled in applying the *materia medica*, one is disposed to question the propriety of exhibiting medicines in any disease. Indeed, the mortality rates have been so great under routine treatment and so small under treatment by cold baths that the intelligent public might reasonably assume that the usual methods were fraught with danger. Nevertheless, the successful treatment of typhoid fever by cold baths, although it lifts a cloud from the medical horizon, brings us no nearer to a solution of the most important question of all—viz.: How are the favorable results brought about? What is the nature of the internal mechanism which enables the economy to withstand and finally eliminate the poison which is assumed to be responsible for the disease? To the reflective mind the answer must come as it has come to me—namely, that the vitality of the system and its ability to resist disease depend upon the integrity and function of the living cell.

I need not invite your attention to the fact that plants, like animals, have cells, but no nerves; but it would be well to bear this in mind, as its importance will appear when we begin to consider the special properties of different remedial agents. It will suffice to note that the epithelial cells lining or covering the mucous coat of the intestine ex-

exercise an important function in the matter of preventing the absorption of poisonous products from the alimentary tract, and whatever contributes to maintain their nutrition enhances the welfare of the entire economy. Admitting these premises and the correctness of the conclusion, one can see with half an eye the wonderful lesson taught by hydrotherapy in typhoid fever, because the functions of these cells are not arrested by the local action of extraneous poisonous products, while their nutrition is distinctly improved by reason of the cold bath sending a surplus of blood to the abdominal vessels, to be returned again to the periphery, and thus the absorption of the products of micro-organisms is reduced to a minimum. Instead of the cold bath, therefore, credit should be given to the living cell for the revolution which has taken place in the method of treating typhoid fever, the bath being recognized as an important auxiliary.

There are two remedies which, from their almost universal employment and frequent abuse, might well form the text of an elaborate contribution, since they possess the property of modifying metabolism in a most remarkable manner. I refer to arsenic and mercury. Both have a prompt and profound influence upon the nervous system when introduced by inhalation; and when taken internally in substantial doses they produce serious tissue changes that are more or less permanent. The fact that they are both active protoplasmic poisons has been overlooked or discounted by the great mass of practitioners; hence the frequent and increasing list of ailments which may be traced to mistaken or misdirected methods of treatment. Whatever effect these remedies exert upon the stomach and its functions, aside from their direct or indirect effect upon the nerve supply, we must bear in mind that both drugs, as inorganic substances, are distributed throughout the economy through the medium of the blood and lymph vascular systems—mercury in the form of an albuminate or oxalbuminate, and arsenic in the form of an arsenite—but the fact remains that the organism protests against their presence and is intent upon their elimination.

In order to form a true conception of the clinical virtues of a drug we must have some knowledge of the effects which it produces upon the various tissues with which it comes in contact, but more especially those structures concerned in its elimination. Mercury, for example, is first eliminated by the liver, although, when introduced into the stomach in the usual manner, doubtless a portion reaches the general circulation without first encountering this organ. Elimination, however, by the liver is but partial, since a considerable percentage of the drug thus excreted is reabsorbed from the intestinal tract, and thus we observe the wise provision of Nature for preventing the too rapid absorption of poisons in any form. Still, the hepatic cells necessarily permit a portion to be carried over into the general circulation. Substantially the same process attends the ingestion of arsenical preparations, and, although both drugs have the effect of producing increased oxidation, they possess special properties peculiar to themselves which can only be hinted at for the present.

Having now traced these drugs to the liver, and stated

that one of their functions is to increase oxidation, the question naturally arises as to the specific effect produced upon this organ and upon its cells by the presence of a foreign body—a protoplasmic poison. To say that mercury, arsenic, or any other drug is an hepatic stimulant, furnishes no evidence which will enable one to judge of the manner in which stimulation is brought about. This method of teaching is too indefinite and should be discarded.

If we were to follow the mercurial or arsenical combination in its course through the hepatic gland, we should find that it enacted the rôle of an irritant to the hepatic cells, and that, if not given in too large quantities, cellular activity would be appreciably increased, which covers the idea conveyed by the term "*stimulation*." But, even then, the explanation does not explain; nor does it lead us to consider the liver, in respect to these foreign bodies, as performing more than a simple mechanical function in a perfunctory manner. We must bear in mind that the hepatic cells exercise the function of eliminants as a specific property, independent of their nerve supply, just as the cells of the stomach and intestines enact the rôle of absorbents independent of their nerve supply. There is a distinct difference, however, between "*irritation*" and "*stimulation*," as applied to the function of these cells. For example, they are excited by an irritant, while they are incited to activity by a stimulant. For therapeutic purposes a stimulant is required, while irritation is followed by pathological processes that retard their activity; and cellular therapy is concerned in promoting stimulation while at the same time avoiding irritation.

Cellular therapy I have defined (*American Therapist*, New York, December, 1892) as "*the name applied to the method in therapeutics of exhibiting properly selected medications with a view to restoration of cell function*," and in practice it is strictly in accord with the deductions of experimental physiology and pathology, but it goes farther than the consideration of the mere mechanical effects of medication. Let us see, then, how its application in the case under consideration may be delineated without recourse to unscientific hypotheses. In the first place, these cells, possessing specific functions, are composed of protoplasm; in the second place, the proper performance of their functions depends upon the integrity of the protoplasmic cells—the elementary substance of which they are composed; and, in the third place, their activity depends upon the capacity of the protoplasmic cells to store up and give off oxygen, or manufacture ozone as occasion demands. Extra work thrown upon them may lessen or temporarily suspend their activity; the ordinary stimulus may be insufficient to promote the customary and necessary metabolic changes (anabolic and katabolic); but a foreign substance, like arsenic or mercury, may be just sufficient to turn the scale by reason of their ability to stimulate or incite the protoplasmic constituents to renewed activity. The question of dosage plays no considerable part in determining the physical facts; but, from a therapeutic standpoint, it is of paramount importance, since the object sought for is stimulation and not irritation. It is now well known that even a mild stimulant, if long continued or given too fre-

quently, may become an irritant, although the "action" is uniform. This axiom is so generally recognized that it is not deemed expedient to point out the necessity for administering the minimum dose, but the frequency of repetition demands attention.

When a readily soluble arsenical product like Fowler's solution is taken into the stomach in substantial doses, it may act as a temporary irritant to the hepatic cells, but if this dose be exhibited at long intervals, the poison is gradually eliminated through other channels, or deposited in the various tissues, thus enabling these cells to recover in a measure from the overstimulation. There is also another factor to be considered in connection with the administration of arsenic in so-called medicinal doses—namely, the increased oxidation which takes place throughout the organism as a whole, which probably has the effect of relieving the liver from a considerable amount of work. On the other hand, when comparatively small doses of an insoluble mercurial, like the biniodide, are taken into the stomach at short intervals, its distribution is less prompt, and the hepatic cells, receiving it in small quantities, find no difficulty in eliminating it, and with it the catabolic products which interfere with its normal functions. In the former case, although the disease may disappear, the patient requires treatment to counteract the effects of medication; in the latter, with the subsidence of the disease, the necessity for medication ceases, because rational treatment is limited to mild stimulation; in other words, it is limited to the restoration of function, and rational treatment assumes, as a prerequisite, that the practitioner is familiar with the peculiar powers of drugs and other remedies.

But these medicaments have a similar effect upon other tissues with which they come into contact; everywhere throughout the economy they produce irritation or stimulation through their influence upon protoplasm, and especially is this noticeable at the points of elimination. It is this property which gives the mercurials their value in nearly all throat affections, since the epithelial cells at this point are actively concerned in their elimination. The same is true of arsenical preparations in the case of pulmonary and bronchial affections. In the course of eliminating these substances morbid products are either destroyed or carried off with the foreign substance. In addition, however, increased cellular activity throughout the organism likewise lessens the work of the eliminating structures, and thus it seems reasonable to conclude that cellular therapy furnishes a basis for scientific therapeutics, since it has for its object the restoration of function through the mechanism of the cell.

There is still another matter to which attention should be directed—namely, the germicidal function of the living cell. Since the promulgation of Metschnikoff's theory of phagocytosis, various views have been advanced to account for the natural resistance of the organism. It has even been claimed that immunity from disease may be due to the natural antiseptic properties of the blood serum; and the therapeutic virtue of animal extracts is still a bone of contention. For the present it will be sufficient to refer briefly to the results of Professor Vaughan's recent inves-

tigations which show, from a scientific standpoint, the exact origin of this important function, or power of resistance. It lies in the cell—not as a whole, but in the cell nucleus—and from this body has already been produced valuable germicidal solutions far more effective than corrosive sublimate and perfectly safe.

This germicidal function of the cell suggests the idea of re-enforcing it when disturbed by disease, by introducing into the system some substance that will enhance its nutrition; but hitherto we have depended exclusively upon remedies which enact the rôle of irritants, as already outlined. Vaughan's investigations form a notable contribution to cellular therapy, and when the time comes that we can make the idea practical, the utility of cellular therapy will be more fully appreciated than it is to-day.

The adaptation of this idea in the rational treatment of disease, although apparently complicated, is extremely simple and easily understood by those familiar with the physiological actions and pathological effects produced by drugs. Text-books and special monographs in medical literature are teeming with the information necessary to guide us in the selection and administration of appropriate medications. Very full and exhaustive reports are to be found in which are recorded all the information required to enable us to decide in a given case as to the remedy and the dose. The only difficulty liable to arise in connection with treatment relates to the complications which may be present, and even here, when the disease is not of long standing, they may be disregarded. The physician on the ground must decide whether it is best to treat the effects or symptoms of disease, or strike at the cause. In the case of many affections, dietetic, hygienic, and climatic regulations will be sufficient to remove the cause, and remedies directed to the effects will promptly restore disordered function. This is especially true in respect to acute diseases and digestive disorders. In the case of chronic ailments physiological remedies are demanded, meaning by this remedies whose physiological action is known to be in line with the desired modifications in cell life and cell nutrition of the affected organ or tissue.

To give this discussion a practical turn may be cited the value of mercurials in small doses in intestinal affections dependent upon a disordered condition of the liver, or throat troubles of like origin; the virtues of arsenic in skin diseases associated with chronic derangement of the alimentary tract, in which instance may be seen a marked illustration of the utility attending increased cellular activity. In every case of disease where the seat of disturbance can be definitely located, remedies may be selected which will modify the function of the cells involved, but our attempts in this direction must be made with due caution, owing to the dangers arising from overstimulation, which would seriously handicap our efforts to restore impaired function.

4621 FRANKFORD AVENUE.

The Tri-State Medical Society of Georgia, Alabama, and Tennessee will hold its fifth annual meeting in Chattanooga, Tenn., on Tuesday, Wednesday, and Thursday, the 17th, 18th, and 19th inst.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & CO.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, OCTOBER 7, 1893.

THE MARINE-HOSPITAL SERVICE.

It seems very unfortunate that the Government Printing Office is so dilatory in its work that the *Annual Report of the Surgeon General of the Marine-Hospital Service for the Fiscal Year 1892*, that was ready for printing on November 30, 1892, should not be issued until October, 1893. The promptness with which these reports have heretofore appeared in December of the year reported on, or at the latest early in the following January, makes the present delay noticeable and likely to cast a reflection on the promptitude of the surgeon general.

The record of the ninety-third year of the service bears testimony to its vigor and usefulness, for it realizes what Dr. Oliver Wendell Holmes said should be desired in advancing years, the service being ninety-three years young rather than ninety-three years old. The admirable organization that was initiated by that able officer, the late Surgeon-General John M. Woodworth, and that was broadened and elaborated by the virile administration of ex-Surgeon-General John B. Hamilton, has had increased responsibilities imposed upon it during the administration of its present executive.

The first portion of this report is devoted to the medical corps, and reference is made to the desirability of legislation making some provision for the families of officers who lose their lives in the discharge of duty, a topic that was recently touched upon in these columns.

The medical work of the service shows that 53,610 patients were treated during the year. Of the 906 surfmen and keepers of the Life-Saving Service examined, 64 were rejected for physical causes; and of 1,344 pilots examined, 60 were rejected on account of color-blindness. But one officer was detailed for cruising duty with the Revenue-Marine Service. The surgeon general recommends that pilots should be re-examined regarding their color-sense every three years, and that a general visual test and a test for hearing should be applied at the same time as the color-test.

Medical officers of the service were on duty at the ports of Boston, New York, Philadelphia, and Baltimore for the examination of immigrants.

There is an elaborate account of the important work of the service during the threatened invasion of cholera and small-pox in 1892. The report on the national quarantine service is especially interesting, as it gives descriptions and illustrations of the various stations.

With all this work the surgeon general has continued the economical methods that characterized the administration of his predecessors, the expenditures for the care and maintenance

of the patients and hospitals being but \$586,839.06, and the unexpended balance increased more than seventy-five per cent. We know of no greater proof of the administrative abilities of physicians than this, for in the Marine-Hospital Service the doctor, not a board of laymen or an executive steward known as a superintendent, is responsible for all the expenditures. Furthermore, there are very few government services that can show a balance from their appropriations at the end of the year.

The volume contains a number of original papers on hygienic and medical topics. One of the most valuable of these is Surgeon H. R. Carter's report on the disinfection of wooden vessels used for the transport of yellow-fever patients. As he is one of the ablest quarantine officers in the United States, his advice can not but prove serviceable to everybody interested in this topic.

An interesting history is published by Passed Assistant Surgeon A. C. Smith, supplementing a report by Passed Assistant Surgeon C. P. Wertenbaker, in the report for 1891, on a supposed case of Morvan's disease. The history as published by Dr. Wertenbaker was typical of that disease, but Dr. Smith reports that over a year later the man presented symptoms that were indisputably those of anæsthetic leprosy. It may be recalled that Zambaco Pasha visited Brittany and found that Morvan's patients that were still alive were affected with anæsthetic and tubercular leprosy, and this case in the United States confirms his statement that Morvan's disease is a form of leprosy.

There are a number of reports of fatal cases, with necropsies, but the value of these is diminished because the name of the reporter is omitted. More careful editing of this portion of the volume is advisable, for, while some of the reports are very well made, others are absolutely devoid of information, and it is not credible that an officer would be willing to append his name to a poor report. The volume contains the usual number of statistical tables, and it is a credit to the service.

CLINICAL INSTRUCTION IN INFECTIOUS DISEASES.

THE "Local Authority" for Glasgow, under the Public Health Act relating to Scotland, addressed, in 1890, a communication to the General Medical Council for Great Britain, urging the necessity of the clinical instruction of students in the characteristics of the various infectious diseases. The Council, at its summer session in June, passed this resolution: "That no qualification in medicine ought to be granted without evidence of clinical instruction in infectious diseases." It seems to us that it would be an excellent plan if the licensing bodies of those States of the Union that have laws regulating the practice of medicine should refuse to license graduates of institutions that fail to provide a course of clinical instruction in contagious and infectious diseases.

At one of the meetings of the New York Academy of Medicine last spring, Dr. John Winters Brannan called attention to this lamentable deficiency in the curriculum of our medical col-

leges, and urged the adoption of some plan by the boards of health of the large cities by which hospitals for contagious diseases should be open for the clinical instruction of students. Dr. Brannan's paper advocated the adoption of *some* plan, rather than any specific plan, his idea being that the boards of health would be strengthened in their conflict with contagious diseases by having practitioners in their respective communities that were conversant with the earlier and with the paradoxical phases of those diseases. Each of the speakers on Dr. Brannan's paper acknowledged that he had begun his professional career with nothing more than book knowledge of most of those diseases.

Our college faculties are fond of laying great stress on the facility their students acquire in recognizing rare diseases that a few men may see once or twice in a lifetime, and on their acquaintance with the technique of operations that not more than a small percentage of these graduates will ever be called upon to perform. But the contagious diseases, that cause about ten per cent. of the mortality in our cities, are only familiar to them through word pictures.

We have heard that the board of health of this city has had under consideration a plan by which such instruction may be afforded, and it is to be hoped that it will not be long before the graduates of New York medical colleges are as familiar with the appearance of any of the contagious diseases as they are with that of pneumonia or heart disease.

MINOR PARAGRAPHS.

A MILK DRESSING FOR BURNS.

The *Chemist and Druggist* states that one of its French contemporaries, the name of which is not given, favors the use of milk as a dressing for burns, to be applied by means of compresses. The dressing is to be renewed night and morning. Under this treatment the reduction of the size of large burns has been marked and speedy. In one instance an extensive burn on the leg, treated in this manner for three or four days, was reduced from five inches to an inch in width. In another instance a severe burn that had been rebellious under a treatment with olive oil and zinc oxide healed rapidly under the application of milk compresses. This suggestion may serve as a valuable one for country practitioners when their accustomed remedies for burns are not at command.

NEWSPAPER MEDICINE.

The journalist's imagination strays into the medical field elsewhere than in the United States. Several of our French contemporaries have recently called attention to the *Libre parole's* account of the case of a woman who had received severe injuries of the head, in consequence of which her brain began to flow out and had to be put back a number of times during the dressing.

AN ACCIDENTAL DEATH FROM AMMONIA.

At New Brunswick, New Jersey, an unusual cause of death has been announced as the result of the careless administration of aqua ammoniac to a person in a fainting condition. A bottle containing several ounces of the drug was held to the pa-

tient's nose in such a way that the liquid was spilled. Some of it found its way into the throat and air passages. The throat and lungs were profoundly irritated by the ammonia, and the woman died in great pain. She had only recently recovered from an attack of pneumonia.

SMALL-POX AND THE VANDERBILT CLINIC.

It has been stated publicly during the past week that two physicians recently contracted small-pox from a patient whose disease had been erroneously diagnosed as chicken-pox at the Vanderbilt Clinic. Unfortunately, the spread of the disease to the two physicians is undeniable, but, on inquiry, we feel assured that the alleged mistake in diagnosis was not made. Our information is to the effect that the case was at once diagnosed as one of small-pox, and that the patient was disposed of in the manner customary in such cases.

THE PUBLIC HEALTH SECTION OF THE ACADEMY OF MEDICINE.

MR. ERNEST HART, the editor of the *British Medical Journal*, is announced to read a paper before the Section in Public Health, Legal Medicine, and Medical and Vital Statistics of the New York Academy of Medicine on Tuesday evening, October 10th. His subject will be Quarantine and Medical Inspection; a Summary of European Experience.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 3, 1893:

DISEASES.	Week ending Sept. 26.		Week ending Oct. 3.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	0	0
Typhoid fever.....	36	8	16	8
Scarlet fever.....	41	5	36	0
Cerebro-spinal meningitis....	1	1	1	1
Measles.....	56	4	32	5
Diphtheria.....	87	31	118	27
Small-pox.....	38	3	7	11

The Philadelphia Polyclinic will devote a special week, beginning on October 30th, to the subject of cataract. Cataract operations will be done, both extractions with iridectomy and simple extraction, and the whole subject of etiology, diagnosis, the dressing and after-treatment, complications, etc., will be gone over. In addition to clinics, demonstrations, and practice of operations on the eyes of lower animals, there will be a series of "conferences" participated in by the professors and the members of the class.

The University of Texas.—The newly created School of Pharmacy was opened on the 2d inst. with a faculty consisting of Dr. James Kennedy, professor of pharmacy and lecturer on botany; Dr. S. M. Morris, professor of chemistry; and Dr. E. Randall, professor of materia medica.

The Richmond, Va., Academy of Medicine and Surgery.—At the next meeting, on Tuesday evening, the 10th inst., Dr. C. R. Cullen is to open a discussion on Obstruction of the Bowels.

The Shelby County, Indiana, Medical Society.—At the next meeting, on Monday, the 9th inst., Dr. J. R. Jenkins is to

present the subject of Excision of the Hip, and Dr. W. F. Green that of Rheumatism.

Ipecac as an Application to Insect Bites.—The *Union médicale* recommends a mixture of equal parts by weight of powdered ipecac, alcohol, and sulphuric ether as an application to insect bites.

Changes of Address.—Dr. William B. Coley, to No. 52 West Thirty-fifth Street; Dr. Frank Hartley, to No. 46 East Thirty-fourth Street; Dr. Louis Heitzmann, to No. 110 East Fifty-eighth Street.

The late Dr. Walter Vought.—At a meeting of the New York Neurological Society, held on October 3, 1893, the following resolutions were adopted:

Resolved, That it is with the deepest regret that this society has learned of the death of Dr. Walter Vought, one of its youngest and most promising members, and one who had already given evidence of the possession of exceptional knowledge and ability, not only in the department of neurology but in the whole field of general medicine.

Resolved, That in the death of Dr. Vought his colleagues lose a friend much esteemed for his excellence as a physician and still more for his good-fellowship, loyalty, devotion to principle, and nobility of character.

Resolved, That this society, in expressing its appreciation of the high qualities of heart and brain of its departed member, and its feeling of regret at his loss, desires in addition to extend its deep sympathy to his bereaved family.

[Signed.] FREDERICK PETERSON, M. D., }
 JOHN W. BRANNAN, M. D., } *Committee.*

The Death of Dr. E. A. Maxwell occurred on September 25th. He was graduated from the Bellevue Hospital Medical College in 1869. Soon after his graduation he was appointed visiting physician to the Randall's Island Hospital and Charity Hospital, and for fifteen years he served as pathologist to the latter institution. At the time of his death he was consulting physician to Randall's Island Hospital and consulting pathologist to the City Hospital.

The Death of Dr. William F. Hutchinson, of Providence, one of the most prominent surgeons of Rhode Island, is reported as having taken place on Monday, the 2d inst.

Society Meetings for the Coming Week:

MONDAY, October 9th: New York State Medical Association (first day—New York); New York Academy of Medicine (Section in General Surgery); Lenox Medical and Surgical Society (private); New York Ophthalmological Society (private); Society of Medical Jurisprudence, New York; New York Medico-historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Boston Society for Medical Improvement; Gynaecological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association; Shelby County, Indiana, Medical Society.

TUESDAY, October 10th: New York State Medical Association (second day); New York Medical Union (private); Kings County Medical Association; Medical Societies of the Counties of Albany (annual), Chenango (tri-annual), Greene (semi-annual—Cairo), Jefferson (quarterly—Watertown), Oneida (quarterly—Utica), Ontario (quarterly), Rensselaer, Schoharie (semi-annual), Tioga (quarterly—Owego), and Wayne (semi-annual), N. Y.; Newark, N. J., and Trenton (private), N. J., Medical Associations; Bergen, N. J., and Cumberland (semi-annual), N. J., County Medical Societies;

Letters to the Editor.

MR. ERNEST HART AND THE AMERICAN MEDICAL PROFESSION.

WASHINGTON, D. C., October 1, 1893.

To the Editor of the New York Medical Journal:

SIR: I have hesitated during the few hours that have elapsed since the receipt of the *Journal* of the 30th ult. whether or not to answer Mr. Hart's inconsequential letter in reply to mine contained in your issue of the 16th ult. He has, however, befogged the matter a little, and a few words from me may perhaps serve to clear away the mist. Mr. Hart, in his recent communication, reminds me of the lawyer who, when he got an adverse decision from the court, satisfied his conscience by abusing the judge.

In regard to the allegations I have made against him, he has nothing but quibbles. As to his personal abuse of me, I am not going to defend myself from anything Mr. Hart can say. My entire conduct has long since been passed upon by the American people and the medical profession, and I and my friends (and I am happy to say I have thousands of them in both categories) are perfectly satisfied with the record as it stands.

I did not assume to represent the medical profession in what I said about Mr. Hart; but I do make that assumption now, and if he will kindly consent to look over some of the many letters I have received from physicians of all parts of the country relative to my observations in regard to him, he will agree with me that, so far as this matter is concerned, I am some-

thing of a representative man. As to my strictures on Mr. Hart's conduct since he has been in this country, I can not for the life of me, after carefully perusing his letters several times, see that he has lessened the force of a single one of them. He says he is the "scientific adviser" (whatever that may be) of the Apollinaris Water Company, but not a stockholder, as I had learned from a warm friend of his. So far as the gravamen of the charge is concerned, no one will seriously contend that he has diminished it in the slightest degree. He is pecuniarily interested all the same, and that is enough, from his point of view, to account for his extraordinary efforts in behalf of the company.

In his plea in mitigation he is like the housemaid in *Mr. Midshipman Easy*, who, when accused by her mistress of having had a baby, replied, "Yes, ma'am, but, if you please, ma'am, it was such a little one."

Mr. Hart says: "I was the guest of the Pan-American Medical Congress, and on entering its headquarters I registered in ceremonious form." Now, can it be supposed for a moment that Mr. Hart imagines he can make the medical profession of this country believe that he mistook a hotel register for the record book of the congress? Every other person present knew perfectly well that the place for registration was at Willard Hall, and that the hotel register was used entirely for the business purposes of the house and had no connection whatever with the congress. If Mr. Hart, who is something of a traveler, did not know this he must have had a sudden accession of simplicity before which that of the proverbial marine pales into insignificance. And the next time he visits Washington and cares to look over the registers of all the hotels of the city he will doubtless find that he was the only medical man so impressed with the desire to register in "ceremonious form" as to make use of titles in such alphabetical improvidence as he displayed.

There is a point in regard to Mr. Hart's connection with the Apollinaris Company on which his admission that he is its "scientific adviser" requires some amplification. I am not one of those self-righteous persons who imagine that pecuniary interest and honesty of purpose are incompatible. To think this is to impugn the integrity of ninety-nine out of every hundred of mankind. But Mr. Hart appears to be one of that class, and he must therefore submit to be judged by his own standard. Now, while he was the "scientific adviser" of the Apollinaris Company he was the editor of the *British Medical Journal*, and was bound, according to his own tenets of morality, to keep the affairs of that company so distinct from his editorial charge that it would be impossible for him to accuse himself of using his position to aid his employers, the Apollinaris Company. Let us see how he fulfilled this obligation.

Looking over the volumes of the *British Medical Journal* from 1875 to the present time we find that there are fulsome advertisements of the Apollinaris and Hunyadi János waters (the latter owned by the Apollinaris Company) ascribing to them, on the testimony of eminent physicians and surgeons with all their medical, hospital, and even literary qualifications appended to their names, more therapeutic virtues than, so far as I know, have ever been given to any other mineral waters, and that, in addition, the reading pages of the *Journal* have contained equally laudatory opinions. Now, every physician who knows anything about these waters is aware that the first-named is a simple table-water, differing from the ordinary beverage merely in being carbonated and containing a little chloride of sodium, while the other is an aperient of a disagreeable taste, no better than a dozen others of this country and of Europe. Yet we find that the *British Medical Journal*, edited by Mr. Hart, for February 22, 1892, contains the following ad-

vertisement, referring to a previous authoritative notice, not an advertisement:

"Its numerous competitors appear to have one after the other fallen away.—*British Medical Journal*."

Again, on page 808 of the *Journal* for March 4, 1876, is an elaborate editorial notice of the Hunyadi János water in which it is especially commended to the favor of the medical profession, and this notice is twice referred to in the index.

And yet again, at the head of a full-page advertisement of this water, in the issue for December 22, 1877, there is displayed in conjunction with others the following testimonial from the *British Medical Journal*:

"The most agreeable, safest, and most efficacious aperient water which has been brought under our notice.—*British Medical Journal*."

This is rather lame English, I admit, but it very emphatically expresses what the writer wanted to say, not one word of which will, I believe, be indorsed by thoroughly disinterested persons qualified to judge.

These citations, which it would be easy to multiply, are sufficient to show that Mr. Hart, when his own actions are involved, has not that keen sense of propriety which he affects when he criticises others. As the editor of the organ of the British Medical Association, holding the views he does, he should not have admitted even the advertisements of the Apollinaris Water Company to its pages, much less have advocated its merchandise in his editorial columns. For was he not an employee of the company and hence contaminated with that pecuniary interest which he believes robs a medical man of his independence and honesty?

Mr. Hart further says: "I do not believe that any details of my medical career have ever appeared in the lay press." Well, if he is at all open to conviction I am able to dissipate his incredulity. If he will refer to the Milwaukee and Chicago papers of the last six months he will, as I am told by medical gentlemen personally aware of the facts, discover several instances in which his portrait and details of his life have been published. These I have not seen myself, but the evidence is to my mind entirely conclusive.

But in the Washington papers published during the meeting of the Pan-American Medical Congress, and while Mr. Hart was present in the city, there is enough to dissipate his unbelief. Thus, the *Washington Post* of September 4th has a portrait and at least half a column of biographical details so full that they could only have come directly or indirectly from Mr. Hart himself.

The *Evening Star* for September 7th refers to him as "one of the best known medical men of England," and gives a full report of his address—so full, in fact, as to lead irresistibly to the conclusion that the writer had had access to Mr. Hart's manuscript.

Now, all these publications occurred under Mr. Hart's eyes without any public remonstrance or protest, and, if not with his active, certainly with his passive, consent. As to the medical journals, we all know that several of them have contained full-page portraits of Mr. Hart, with minute biographical details not previously known, probably, to a dozen persons in this country.

So far as my opinion goes, I have only to say that I see nothing objectionable in all this. Mr. Hart has led a busy life, he has doubtless in his day accomplished a great deal of good; and there is no reason whatever why the American people and medical profession should not be made acquainted with his works of reform and progress. But it is scarcely fair for him to reprove in some of us (Dr. Pepper, Dr. Hughes, Dr. Love, Dr. Gihon, Dr. Wyman, Dr. Hamilton, Dr. Ohman-Dumesnil,

to mention a few of those whose portraits and biographies appeared with his) what he tolerated in himself.

There is not much more to say at present, for Mr. Hart in reality admits the truth of all the other statements of my letter. But, in referring to what I said relative to the treatment of our English brethren by society, he says my remarks are a "parody." Certainly this is an instance of heterophemy. They were solemn facts, not one of which Mr. Hart or any one else can truthfully deny. Should he attempt to do so, I am prepared to substantiate them, not only from the statements of the victims themselves, but from unimpeachable literary and medical sources, and even from the journal which Mr. Hart has so successfully edited for over a quarter of a century.

I should like to say a word or two in regard to the detection by Mr. Hart of the impurities existing in the water supplied to Chicago and of the change effected through his influence with the authorities. I was not aware till I read his article in a recent number of the *British Medical Journal* that the physicians of that city had neglected their duty or were so ignorant as not to know what it was or how to perform it, but now that I am aware of what he accomplished in that direction I trust that I am duly grateful. To use his own language, he was "able to demonstrate an undeniable relationship between the preventable diseases of the city and its pollution of the lake and to demonstrate some incredible shortcomings in this matter which have greatly moved public opinion." But I must forbear lest I weary your patience.

In conclusion, let us hope that, having no social, or unsanitary, or unprofessional foes to conquer at home, Mr. Hart, now that he has so auspiciously begun the work of reform among us, will stay long enough to finish the good work and thus to render us a worthy daughter of the immaculate mother who gave us birth.

WILLIAM A. HAMMOND, M. D.

THE NEW YORK INFANT ASYLUM.

NEW YORK, September 30, 1893.

To the Editor of the *New York Medical Journal*:

SIR: The resignations from the medical board of the New York Infant Asylum and recent comments in one of the New York daily papers lead me to send you the resolutions adopted at the last meeting of the defunct board, authority to publish which was given me at my discretion. I have hitherto refrained from doing so for the reason that I did not see any good to be gained by washing what doubtless the board of managers will term "dirty linen" in public. In view, however, of the reported comments of certain of these managers, it seems eminently fitting that medical men should understand distinctly the causes which led to wholesale resignations from one of the greatest charities (using the term in its true sense) in the city, for thereby alone will medical men be enabled to judge as to whether their self-respect as men and as physicians will allow them to fill the vacant places under the present management. Medical men may be cheap, as it has been stated, but when a principle is at stake medical men ought to stand together and thereby furnish a living denial of the allegation. All positions are not golden ones, and official titles at the cost of one's self-respect are unworthy of our acceptance.

I append the resolutions:

Whereas, The medical board of the New York Infant Asylum respectfully requested the board of managers:

1. No faithful medical officer shall be removed without cause.
2. Nominations to fill vacancies shall emanate from the medical board.

Whereas, These reasonable and just demands have been peremptorily refused by the board of managers,

Resolved, That, in dignified protest and in justice to themselves as men and physicians, the following members of the medical board hereby resign.

These resolutions were signed by eighteen medical men who for years had given their time, their skill, and their money to the institution. These resolutions were adopted after nearly six months' fruitless endeavor to adjust matters amicably and equitably. This action is now characterized as "tomfoolery." One of the managers is reported to have said that he did not care a "picayune."

The medical profession may now judge for itself. The gentlemen who resigned have absolutely no nuts to crack. They left the institution they had served well with regret and they wish well to those who succeed them.

EGBERT H. GRANDIN, M. D.

Proceedings of Societies.

FIRST PAN-AMERICAN MEDICAL CONGRESS.

Held in Washington on Tuesday, Wednesday, Thursday, and Friday, September 5, 6, 7, and 8, 1893.

SECTION IN GENERAL SURGERY.

(Continued from page 323.)

Suturing of the Brachio-cephalic Vein.—Dr. MARIN, of San Pueblo, Mexico, read a paper with this title in which he described that, on the 1st of May, 1889, a man was received at the hospital of the city of Pueblo who had been wounded by a pistol bullet of forty-four caliber. The bullet had made four wounds. It had first entered at the sternal portion of the left sterno-clavicular articulation. The second, an exit wound, was upon the right clavicle at the juncture of the inner and middle thirds. The ball had then entered again at the shoulder three centimetres below the acromion in the anterior portion, and had made its final exit at its external aspect, one centimetre below the acromion. The left sterno-clavicular articulation had been opened, the ball traveling in the subcutaneous tissues of the anterior part of the neck, afterward backward to the right sterno-clavicular muscle, and again upward to its clavicular insertion. The shoulder wounds were of no importance. The speaker was in attendance upon the man two hours after the accident. The patient was pale, bloodless, in a condition of syncope, with cold sweats, and had a small, frequent pulse. The hemorrhage had been very profuse, and dark blood was pouring from the supraclavicular opening. The flow of the blood was peculiar, as it would stop on inspiration when the man remained quiet; then the loss was insignificant. Immediately after any effort the quantity was increased. With the assistance of Dr. Gonzales and Dr. Lopez the speaker had proceeded to an examination of the wounds, and particularly of that wound which bled so much. It was found that the seat of the hemorrhage was deep and probably in the veins at the root of the neck, and that it would be necessary to make a dissection of the sound tissues until the bleeding point was located. The clavicular portion of the muscle was carefully cut above its insertion, when it was ascertained that the bleeding was still deeper. A further layer of muscles was accordingly dissected with the finger and, by carefully sponging, the bleeding point was at length seen. Hemostatic forceps were applied and an attempt was made to pass a ligature, but the effort was unsuccessful. Further examination revealed a longitudinal fissure of the vessel, one centimetre in length, running

between the junction of the internal jugular and the subclavian veins, at the point where they form the brachio-cephalic vein. This was the point from which the blood had poured during expiratory efforts. Compression by sponges was made, and a consultation held as to the best course to pursue. Ligature at the site of the bleeding had been tried and had failed, and to ligate all the veins coming to the large trunks was almost impossible. Compression with a gauze tampon was an uncertain and dangerous measure. The speaker had at length resolved to suture this large vein. Fine, slightly curved needles charged with catgut were accordingly introduced after cleansing the parts. The hemorrhage was immediately arrested, and, despite the struggles of the wounded man, no more blood was seen. The sutures were passed through the entire width of the wall of the vessel. Some days subsequently the cut muscle was sutured. Everything progressed well and the man was out again in a month. There had been no resulting thrombus or interrupted venous circulation.

The speaker then reported another case in which he had, in July of this year, operated upon a man fifty years of age for carcinomatous ganglion of the right thigh. It was found that the saphena was involved in the degeneration, and, notwithstanding its previous ligation, extensive bleeding resulted during the process of extirpation. The cruralis was also injured. Hemostatic forceps were applied to the walls of the vein parallel to its direction sufficient to embrace the opening without shutting off the lumen of the vessel. Under the forceps the speaker then passed two catgut mattress sutures with a very fine needle, taking care not to perforate the adjacent artery. All the bleeding was thereby stopped. The patient was getting well when the speaker had left home.

Dr. MARCY thought the paper pointed to a distinct advance in surgery. Very little attention had been paid to the possibility of suturing veins. The mattress suture had been a happy thought. Very little would control hemorrhage in veins, and the use of a continuous Lambert suture, going through the edges of the wound without perforating them, would be effectual.

Two Cases illustrating the Value of Gastrostomy for the Exploration of the Cardiac Extremity of the Stomach.—

This was the title of a paper by Dr. EENESE LAPLACE, of Philadelphia. The author said that the following cases would, he thought, illustrate the benefits to be derived from immediate operation for the relief of symptoms, in spite of the desperate nature of the conditions present. Gastrostomy for the relief of an oesophageal stricture had the reputation of being something in the nature of a *dernier resort*, and this might possibly be the case when the stricture was of a cancerous nature. Still, owing to the impossibility of a positive diagnosis, it might happen, as in the cases to be cited, that other causes were producing the stricture, which, if the patient could be tided over a crisis, would subside, and the patient be restored to health.

J. H., aged fifty-four years, had been healthy all his life until the time when he began to notice a difficulty in deglutition, which was soon followed by vomiting whenever the attempt was made. Finally he was unable even to swallow water. No stomach tube of any size could be introduced past the stricture, which was diagnosed as being situated at the cardiac extremity of the stomach. No cancerous history and no possible clue could be obtained as to the nature of the obstruction. On entering the hospital the patient was in a starved condition, having been fed by enemata for three months. Although he was very weak and almost exhausted, it was determined to perform a gastrostomy. An incision was made on the right side, three inches in length, parallel to the costal arch, starting about half an inch from the ensiform cartilage. On opening the peritoneum, a hard, glistening mass was seen, and this was recog-

nized as the stomach only by its attachment to the omentum. This mass was accordingly sutured to the abdominal wall by twelve silk sutures, leaving an exposed surface of the stomach of about three quarters of an inch diameter. On the third day this was punctured with the thermo-cautery, and a sound was passed into the stomach, which was found to be quite thick and strongly contracted. The patient was fed through this opening with peptonized milk, custards, and so forth. In a few days the stomach was much dilated, and then the patient, craving food, was allowed to chew what he was given to eat, and the mass was then introduced into the stomach through the opening. No difficulty was found in withholding the contents of his stomach, for a plug, consisting simply of an India-rubber nipple such as is used in ordinary feeding bottles, was introduced, and remained clasped in position by its hour-glass portion. The patient had rapidly increased in weight and had regained perfect comfort. Then, to the astonishment of those watching the case, he had become able to swallow food through the oesophagus. Being in apparently perfect health, it was determined to close the fistula in the stomach. The patient was anesthetized, and an effort was made to determine, if possible, what had produced the original stricture. Two fingers were introduced into the stomach toward its cardiac extremity, when a pedunculated mass was found hanging high up and out of reach. Obstruction to the oesophagus had evidently begun at the time the growth started. The mass was without doubt a polypus, which had originated at the cardiac extremity of the stomach as a sessile growth large enough to completely obstruct the orifice, but, on further development, becoming pedunculated, had gravitated into the stomach, leaving the oesophagus free. The patient at the present writing was feeling perfectly well, and still retained this growth within his stomach, though it afforded him no inconvenience. It would, in the author's opinion, eventually become digested should its pedicle become long enough to allow it to hang on the floor of the stomach. If the patient should suffer inconvenience from its presence, the growth could be removed without difficulty by cutting down on the line of the old cicatrix.

The second case was that of A. H., aged fifty-two years, a miner by occupation, suffering from tertiary syphilis. This man had gradually lost the power of deglutition, but was otherwise in a fair condition. On examination, an oesophageal sound of the smallest size could not be passed through the cardiac portion of the oesophagus. There was great emaciation, and, for the relief of the progressive starvation, gastrostomy was resorted to. The operation was performed at two separate sittings, and the details were in effect those of the previously recorded case. After two weeks the emaciation had considerably disappeared and the opening in the stomach had enlarged to the size of a five-cent piece. No apparent change had taken place in the patient's power of deglutition, although he was given mixed specific treatment by the stomach. It had then occurred to the author that it might be possible to introduce a sound through the opening in the stomach and so into the oesophagus from below upward. This was tried, and with success, beginning with the small sizes. On the third day dilatation was continued, and the patient was then able to swallow liquids with ease. In about a week alimentation was completely carried on by the mouth, and the patient submitted to the operation of closing the fistula. The man had since gained flesh, and was now in good health.

These two cases, the author thought, illustrated not only the value of gastrostomy as a means of supplying nutrition to the body, but also of exploring the stomach in its whole dimension. This latter idea, as applied to the pathology of the cardiac extremity, had, he thought, not been given adequate atten-

tion, and he would be amply repaid if others were also enabled to find a solution to some pathological problem of this region by the opportunity for exploration afforded by gastrotomy.

Tapping the Lateral Ventricles of the Brain.—Dr. J. FRANK, of Chicago, presented a paper so entitled. After reviewing at some length the literature of the subject and citing cases and the opinions of authors, the writer went on to say that the interesting train of symptoms, long known and recognized—of which the principal were nystagmus, general convulsions, disturbance of the respiration, slowness of the pulse, vomiting, coma, and death—found a solution in the acceptance of the theory of compromise of the brain function by so-called intracranial pressure. Whether this pressure actually existed, or whether the symptoms had for their foundation irritation of brain elements by increased transudation, was of less importance than the possibility of the restoration of the lost brain function in part, or wholly, by removing collections of cerebro-spinal fluid, blood, pus, or other foreign matter. Tapping for hydrocephalus through the fontanelles was so old a procedure that it could not be determined who first devised or practiced it. Tapping the ventricles by means of trephining was of more recent date, and the method had been technically perfected and shown to be easy of accomplishment. After describing in detail two successful cases recently operated upon by himself the author said that there was a point of election for reaching the ventricles; either of Keen's routes would make attainment of the object easy. They should not, however, be considered the only manner of finding the cavities, nor was it necessary to have recourse to them when the skull had been opened in a different place for injury or disease. From any point on the cerebral cortex it was not very difficult to puncture to the normal ventricle. Familiarity with its location and formation being the principal requirements, it was easy where the cavity had been enlarged, as in chronic hydrocephalus.

After the usual aseptic and antiseptic details of preparing the head a crucial or curved incision, involving a flap, might be made to expose the cranium. A chisel, drill, or trephine, large or small, might be used. If the opening was too small, it might be enlarged with proper instruments. The dura might be simply punctured with a trocar or a dural flap made to expose the cerebral surfaces. This latter had the advantage of allowing closer observation of the cortex and of finger exploration between the cortex and dura. The instrument to be used for the puncture was optional with the operator and the depth of the puncture must depend upon the amount of fluid in the ventricle. Then came the very important question of drainage. Should it be rapid and free, or slow and in drops, and should there be irrigation? These questions would have to be decided to suit each individual case, as the requirements for each must necessarily differ. If the effusion into the ventricle was the result of acute and still active inflammation, the relief of compression by rapid removal of the fluid and continuous drainage until the acute stage subsided, or repeated tapings without drainage, would be a rational procedure. If the inflammation was in the stage of retrogression, the removal of fluid by simply tapping without drainage would be sufficient. In cerebellar tumors, or tumors in other situations, blood clot from trauma, etc., compromising the circulation to the extent of bringing about a hydrops ventriculi, if the condition was recent, rapid and continuous drainage should be employed. If it was of long duration, with a great amount of fluid, where the brain tissue was or might be atrophied, tapping and slow continuous drainage, or repeated tapping, would seem to be indicated. In chronic hydrocephalus with great distention of the ventricle, the brain tissue being atrophied and greatly altered in physical relationship, in order to allow of gradual return to something approaching normal condition, it would be

best to both tap and drain slowly. Rapid emptying of the ventricle under these circumstances might be fatal.

In abscess of the brain breaking into the lateral ventricle, the most rapid and free drainage and cleansing irrigations were the only procedures promising relief in that most dangerous condition. In these cases it would be best to trephine and drain both sides and irrigate from side to side. Repeated tapings or aspirations might in some cases take the place of drainage. The means to secure drainage would be found in rubber tubes of different caliber, gauze, wicking, or horse-hair. In special cases operative procedure could go further than puncture or drainage. The ventricles might be incised and opened with forceps so that any consistent mass or foreign body might be removed. When the skull had been opened for compression symptoms, which were confirmed by bulging of the dura and protrusion of the brain, and no tumor or clot or depressed bone being found, it would be indicated to tap the ventricles. In chronic hydrocephalus, with enlargement of the head, with great distention of the ventricles and corresponding atrophy of brain tissue, tapping and drainage would be indicated. The following conclusions were therefore arrived at by the author of the paper:

1. For distention of the ventricles, for acute, simple, or tubercular meningitis, tapping the ventricles is a therapeutic measure clearly indicated, and, other things being equal, promises recovery.
2. For effusion of blood into the ventricles, from trauma or disease, the operation makes recovery a possibility.
3. For abscess, involving the ventricles, it is imperatively demanded.
4. In effusion into the ventricles from brain tumors it may offer relief to symptoms.
5. For chronic hydrocephalus, with moderate distention of the ventricles, without enlargement of the head, it may afford relief.
6. For chronic hydrocephalus, with great distention of the ventricles and enlargement of the head, the operation will lead to fatal results.

The PRESIDENT of the section asked if, in cases of distention from acute hydrocephalus, the author of the paper had tried laminectomy.

Dr. FRANK said he should deem such a measure feasible in a condition of general distention.

Dr. LAVISTA, of the City of Mexico, expressed high appreciation of the work reported by Dr. Frank. He thought that in such cases simple trephining did not give a sufficiently wide area for work, and that the skull might advantageously be still further removed by craniotomy measures.

The Uses and Abuses of the Drainage-tube.—Dr. H. O. MARCY, of Boston, read a paper with this title. He said its object was to ascertain if we already possessed the requisite data from which we might draw deductions and formulate rules for guidance in the employment of drainage in wounds.

Basic to the fundamental consideration of the subject was the condition of the individual, the character of the injuries sustained, and the complications incidental thereto. The vital force, the individual resistance, varied in every instance, and must remain an *x* factor in every personal equation. It was this power in these reserved energies which was called into action in the repair of the structures after injury. In the struggle for the survival of the fittest the individual organism was ever at warfare with its surroundings, and the struggle for the mastery of the living over the dead was waged at the site of every injury, which was the battlefield where were brought into play the most subtle and occult processes of organic life.

The speaker, after referring to the general practice in the use of drainage, and quoting many of the authorities on the subject, went on to say that the object of drainage was to remove safely from a wound deleterious substances which, if allowed to remain, would in a greater or less degree retard cure. The infected material not only became dangerous in itself, but generated a chemical poison which in amount was often sufficient to produce death. To what degree the living tissues were endowed with resistant power for self-protection could perhaps never be determined with accuracy. It was, however, settled beyond a doubt that the healthy structures did have power to a certain extent to resist bacterial invasion, and that this power was in a more or less direct ratio to the physical vigor of the individual. Age, condition, and the phagocytic power of the cells to destroy bacteria under favorable conditions were also valuable factors in aiding the preservation of life. It was important that the surgeon should devitalize as little as possible the remaining tissues and that he approximate carefully cleaned surfaces. Was the present state of operative procedure sufficiently accurate to warrant the assertion that complications could not supervene? This was a question which must first be satisfactorily answered before we would be in a position to determine positively when, in aseptic wounds, we should employ or discard drainage. It was certainly clear that the experience of the past twenty years had been leading toward the solution of this problem until now it seemed demonstrated beyond a doubt that an aseptic wound might be made in aseptic tissues and maintained aseptic until restoration was complete. If this was true, the *modus operandi* of modern wound treatment must be mastered, as a ritual service of a higher religion, before a surgeon was competent to enter upon the serious responsibilities of his office. If aseptic conditions were maintained, then we might safely conclude that the drainage of the wound would not be necessary, and, if unnecessary, certainly undesirable. At best, the drainage-tube was a foreign body and its presence in a wound prevented primary union of that portion of the tissues which inclosed it. It kept the wound to a certain extent an open wound, and, as such, made secondary infection so probable that the most careful antiseptic dressings were required to absorb and disinfect secretions and prevent atmospheric contamination. In an aseptic wound, after the removal of a tube, the final closure of the tract was comparatively slow and by granulation. These were well-recognized objections, and efforts had been made to overcome them by many ingenious devices. If drainage was to be discontinued in aseptic wounds, it must be accepted that the greatest care should be exercised in leaving as little devitalized tissue as possible and in evenly coaptating the divided parts. The wound should be clean and dry. The different layers of the tissues should be joined with as little injury as possible and the external wound protected from infection. To reiterate, to secure the best results it was important to have clean incisions, devitalizing as little as possible the structures, minimizing irrigation, sponging, compressing with artery forceps, retractors, and so on, and to rejoin with careful coaptation the divided structures by light, running, continuous, buried catgut sutures. The skin was easily coapted by a similar buried suture taken from within outward through the deeper layer only. The wound should be sealed with a germ-proof layer of iodoform collodion, re-enforced by a few fibers of cotton. Such wounds went on rapidly to repair without oedema of the tissues, pain, or even tenderness, and the resulting cicatrix was minimized.

Were all aseptic wounds in healthy organisms to be thus treated? Without a doubt, as experience abundantly demonstrated; but the affirmative to such an important question was undoubtedly to be maintained only by the most scrupulous of

aseptic measures. When in doubt, it might be better to drain large wounds, but the speaker could not question that he who used the drainage-tube in aseptic wounds unconsciously confessed thereby his lack of confidence in his ability to maintain an aseptic condition. In dealing with wounds the first consideration should be the safety of the patient. This was best conserved by a careful estimate of the individual and his circumference, his possible internal and external foes. The highest theoretical condition for wounds was their restoration as nearly as possible to the normal condition of the tissues and their retention at rest in an aseptic condition. This, in a great majority of wounds, rendered drainage not only unnecessary, but of positive detriment and a source of danger.

Complete closure of an aseptic wound by aseptic buried animal sutures, retained at rest by a germ-proof dressing, came nearer to the ideal than any method yet devised. There was no fear of hemorrhage in an aseptic wound thus closed. There was no further danger from infection; clumsy antiseptic dressings were entirely avoided, but little further care was necessary on the part of the surgeon or attendant, and the patient was relieved from fear of subsequent suffering from the removal of stitches. Stitch abscesses were impossible and the patient was free from pain and went on to rapid convalescence. The author was sure that a better knowledge of the condition of wounds would restrict the use of the drainage-tube almost entirely to septic wounds and that operative wounds in aseptic tissue would be aseptically maintained by primary closure, without drainage.

Dr. QUIMBY, of Jersey City, said that the drainage-tube was a foreign body, and as such was frequently a source of danger to wounds which might otherwise heal by first intention.

Dr. McCRAE, of Georgia, had not found iodoform collodion do so well if applied over bony prominences.

Dr. PREWITT, of St. Louis, thought that, as surgeons were not now so primarily septic, drainage-tubes were not as generally in use. He agreed that in those cases where a septic condition existed drainage was imperative. Any abdominal secretion would show in a few days that the tubes were infected with germs. There was no absolutely fixed rule, but drainage had probably been used too much and injuriously.

Dr. McCOSH thought that every modern surgeon would feel indebted to Dr. Marcy for his insistence in the matter of improved wound treatment. His own practice was to dispense with drainage-tubes in every wound which might be considered aseptic. If there was an element of doubt, it was better to leave the drainage-tube in for one or two days. In very large wounds, where there were extensive dead spaces, it was unwise to sew up or tie too tightly. Some strands of silkworm gut might be introduced, or rubber tissue, but not a drainage-tube. He was in the habit of flushing out the abdominal cavity and had never regretted doing so.

Dr. LAPLACE thought that the millennium of surgery would be reached when interference with Nature's processes was reduced to a minimum. Drainage was only indicated when, either before or at the time of a surgical procedure, Nature had been interfered with. He agreed that drainage must be provided for if we expected infection, but to-day we ought not to expect it.

Dr. MYER, of San Francisco, could not agree that drainage was a thing of the past. We should always have wounds requiring special treatment in the way of drainage. It was not always possible to command coaptation of the walls of a perfectly aseptic wound, and if secretions were allowed to flow into cavities, and unavoidable oozing took place, there resulted a perfect culture medium. He did not think there would ever

come a time when the drainage-tube or packing could be entirely dispensed with.

Dr. WILDING, of New York, while believing that in septic surgery and knife wounds drainage should be unnecessary, thought there was a class of cases in which it would have to be employed. He did not like the drainage-tube, but preferred some absorbable material.

Dr. FRANK, of Chicago, said that since Dr. Marcy had urged sepsis as almost a *sine qua non* in the treatment of wounds, he had been making every effort to attain such a desirable result. He was, however, bound to admit that he had failed to get more than fifty per cent. of union by primary intention. He had endeavored to keep his technique faultless, and had then closed up apparently aseptic wounds. The next day there would be a little rise of temperature. He thought that auto-infection was a most important factor, and he believed he could trace trouble to the hypodermic injection. He thought that it was the duty of surgeons before operating to have their patients well overhauled as to their general condition, and did not see that there was any harm to be expected from a drainage-tube if such was favorable.

Dr. LAVISTA agreed to the conclusions reached by the author of the paper, but thought that the general organism of the patient would often play a most important part in determining results after an operation, notwithstanding any scientific endeavor on the part of the surgeon.

Dr. PANCOAST thought that every practical surgeon would agree in the main with the author of the paper. It must, however, not be lost sight of that from any large wound made with a sharp-edged tool there must be an effusion of serum, and though Dr. Marcy expected this wound to close up without such secretion, the speaker would prefer to feel that there was provided for a short time some proper means for the absorption of those unavoidable discharges.

Dr. MARCY then pointed out that the desirable result was not attained in too many instances, because surgeons did not give sufficient attention and take sufficient time in perfecting the toilet of the tissues before closing wounds.

(To be concluded.)

SECTION IN GENERAL MEDICINE.

The President, Dr. VICTOR C. VAUGHAN, of Ann Arbor, Mich., in the Chair.

(Concluded from page 387.)

Vaso-motor Ataxia.—Dr. S. SOLIS-COHEN, of Philadelphia, read an abstract of a paper on this subject. He said that by the term vaso-motor ataxia he proposed to designate the condition of instability of the mechanism of circulation present in certain persons and characterized by abnormal proneness to disturbance, with tardiness of restoration, of the equilibrium of the cardio-vascular apparatus. The manifestations of these conditions were most strikingly displayed in the terminal vessels, and occurred chiefly under the action of external influences. The stimulus might be applied centrally or peripherally, but in each case the resulting phenomena indicated a defect of central inhibition. Vaso-motor ataxia was in many cases congenital, in some inherited, and it was not uncommon to find it present in several members of a family. In some cases the phenomena were parietic and in others spasmodic in character. Usually the two kinds were displayed in varying degree in the same patient; it made no difference, however, whether spasmodic or parietic, the symptoms were suggestive of inco-ordination. In exophthalmic goitre, especially such cases as were produced by emotion or were markedly intermittent, was found the extreme type of the parietic variety of vaso-motor ataxia. The form of

Raynaud's disease known as "local syncope" furnished an extreme type of the spasmodic variety, while "local asphyxia" exhibited both spasmodic and parietic phenomena. Between the extremes there were numberless gradations down to the slightest departure from the normal. Even the extreme symptom groups represented merely exaggerations of phenomena that, under certain conditions, occurred in normal individuals. Dermographism was an essential feature of vaso-motor ataxia, and in most cases factitious urticaria could be readily produced by cold or by pressure, or by both. Mottlings of the skin, certain peculiar markings of the nails, telangiectases, and stigmata were common. Where there was this defect of central inhibition there was usually a hemorrhagic tendency, as shown by ecchymoses, petechiæ, epistaxis, hæmoptysis, hæmatemesis, hæmaturia, and retinal hæmorrhage. Even in the absence of hæmaturia, red blood-cells were often found in the urine. Uric acid, urates, and oxalates were likewise common. The presence of albumin, tube casts, and cylindroids was less common and was usually intermittent. Glycosuria had also been observed. In many striking cases there had appeared to be a morbid alteration of the thyroid gland, as seen in Graves's disease. The action of the heart was usually rapid, irregular, and easily disturbed, palpitation was common, and in some cases intermittent tachycardia had been noticed. Hæmic and functional murmurs were occasionally heard. Among other symptoms and morbid associations observed were drug idiosyncrasies, urticaria, local oedema, angina pectoris and pseudo-angina, hyperidrosis, asthma, hay fever, vertigo, migraine and other forms of headache, transient hemiopia and other visual disturbance, persistent mydriasis, astigmatism, myopia, hyperopia, menstrual irregularities, intermittent polyuria, rheumatism, chorea, epilepsy, neurasthenia, gastralgia, enteralgia, and membranous enteritis, most of which were doubtless related as effects of a common cause or as secondary results. The development of pulmonary tuberculosis in some cases was probably a sequence of vascular and trophic disturbance in the lung. The author believed that the time would come when the many diseases of obscure origin could be traced to the sympathetic nervous system. Once attention was turned in that direction, the cases were given careful study, and a series of microscopical examinations was made, a great step in advance would have been taken in the pathology of these diseases.

Dr. MANUEL CARMONA Y VALLE, of the City of Mexico, said that he had had quite an experience in the class of cases designated as vaso-motor ataxia. In one of these the vaso-motor symptoms had been exhibited by a unilateral redness, sweating, and oedema. He had always supposed the disease to be due to a disturbance of the sympathetic nervous system.

Dr. WEST thought that the name vaso-motor ataxia, as applied by Dr. Solis-Cohen, was one that would be of considerable worth to the general practitioner, in that it simplified one's appreciation of the class of disease referred to. He had seen several cases which would come under the category of vaso-motor ataxia—for example, flashes of heat, localized sweating, redness, etc. He thought that some cases of insomnia could be attributed to this cause. As the causes of these conditions had always been so obscure, he was glad that Dr. Solis-Cohen had advanced an idea that might lead to work being done in the right direction.

Dr. SOLIS-COHEN said that it was his belief that vaso-motor ataxia was congenital and due to imperfect development. This would account in many instances for its obstinacy in resisting treatment and the apparent futility of any measure directed to the improvement of the condition.

The Filaria Sanguinis Hominis.—Dr. DE SAUSSURE, of South Carolina, demonstrated the filaria as found in the blood

of the colored people in Charleston. He also exhibited some specimens of the adult worm taken from the cavity of the heart of a patient who had died from general anasarca and exhaustion. The disease was peculiar to the southern countries of Europe, but had never been found to exist to any extent in this country until the author's investigations. He now had discovered that the existence of filaria in the blood was not confined to the colored people, and was not only increasing in that class but was to be found in the whites living in the same locality. The embryos were to be found in the blood only at night, and this was proved to be positive, as the habits of persons had been reversed to see if the filaria perhaps had any association with meals, sleep, etc. They could be found in the domestic dog both day and night, and also in the mosquito. It was impossible to say whether the dogs in that vicinity contracted the disease from the people, or *vice versa*. As for the mosquitoes, they might have extracted the blood containing the embryos from man, or they might have ingested them from the waters in that region, and really be the means of communicating them to man. The filaria was very easy of discovery; a drop of blood from the end of the finger placed under the microscope with a power of fifty diameters would disclose an organism with a rounded head and a sharp tail, and four hundred diameters would show some of the same structure as seen in the adult worm. The speaker thought that it was not improbable that the disease was brought about by the use of inferior drinking water, as the condition was almost exclusively confined to the lower class of colored people who lived in a very depraved way and drank water from swamps and sloughs. As a great many of that class of people died from dropsical affections, it was not at all unlikely that the disease was more prevalent than had been supposed. Chylocele, chyluria, and hæmaturia were some of the symptoms of the presence of the filaria in the blood. Patients suffering with any of these conditions should in every instance be examined for the filaria, especially if the known habits were depraved or the persons had been forced to live in bad hygienic surroundings and drink inferior water. In a description of several cases that had attracted particular attention, the author referred to an examination of the fluid in a case of hydrocele showing the embryo of the filaria, and in another where the patient was suffering from chyluria, and the urine contained the organism. Dogs in the South frequently died from dropsical diseases and general anasarca, and the autopsy revealed the adult worm. The author described the very interesting case of a negress whose blood during pregnancy showed the presence of the filaria up to the time of the beginning of labor; during labor they could not be found, although repeated examinations were made. Examination of the child's blood immediately after birth revealed no embryo. The filariae did not reappear in the mother or appear in the child until thirty days after confinement, when they were found in great quantities. Examinations of other members of the family showed filaria. In a summary of the facts in regard to the presence of the *Filaria sanguinis hominis*, the author said there was no doubt that the disease was rapidly increasing in Charleston. The colored males were more susceptible to it than the females, and it was beginning to be found among white people. A case was related of a Northern man, in the best of health, who had gone to Florida to open up some phosphate fields two years previously, and whose general health had so failed that he had repaired to Charleston for treatment. The author had examined the blood for malarial germs and discovered the embryo of filaria. This man had been obliged to drink inferior water and had been very much distressed with mosquitoes and fleas. That the disease was not hereditary there seemed to be no doubt. There was no pathognomonic sign of the disease, except that of microscopical confirmation,

and that only at night. Many of the symptoms due to malaria might be present in the disease. If there was any symptom more frequent than another it was that of chyluria or dropsy. Increased heart action and heart murmurs were present. In some cases there might not be any deviation from the normal, and yet when the blood was examined the filaria be found. In one case that had come to autopsy, in which the filaria had been seen during life, no adult worms could be found. The patient had died from marasmus, brought on, no doubt, by the presence of the embryo in the blood. So far, no form of treatment had seemed to exert any influence upon the parasite. It was thought that the only hope would be some form of medication that would gain an entrance into the blood through the respiratory tract. It was found that if water was added to blood containing embryos they were dissolved; they seemed to melt in a watery solution.

Dr. FELL, of Buffalo, said that, while he knew that these embryos had been found only at night, yet he did not think that they could be altogether absent in the daytime. Probably there was some fault in the technique which had failed to discover them in daylight. If it was really a fact that they were present only at night, what scientific explanation could there be for such a phenomenon?

The PRESIDENT said that, while the geographical distribution of filaria was well marked, isolated cases had occasionally cropped up. One case had recently come under his notice in Canada. The patient had lived all his life in one district, and, so far as was known, had never come in contact with people from tropical climates that might have had the disease.

Dr. DE SAUSSURE said in reply to Dr. Fell that, if the examinations for filaria had only been made by one observer, there might be a doubt as to the correctness of the knowledge gained, but when all the investigators had failed to find the embryo in the daytime, there was no doubt that they were absent. The author had examined thirty-three cases, but had never found them in the daytime; he had been able to discover them, however, as late as at ten o'clock in the morning and as early as at five in the evening, but at no other time during the day. It had been suggested as a form of treatment that venesection be tried, with the transfusion of a saline solution. Chloroform narcosis had been resorted to, but the effect on the filaria had been imperceptible. Death usually took place from some slow, exhausting disease in from two to three years.

The Cholera Asiatica of 1892.—Dr. J. DRUMMOND BURCH, of Aurora, Texas, reviewed the history of the epidemic of cholera of last year. He said that so long as the mud of the Ganges was sacred, so long would cholera trouble the earth. The disease was distinctly traceable to an endemic of cholera in India—first in Djelalabad, Afghanistan, a town largely Hindu, in December, 1891. Pilgrims carried it to the great Hurdwan Fair, about two hundred and fifty miles north of Lucknow, by March or April, 1892. Thence, "commerce having been ingrafted on religion," it traversed much of the route of 1831, as shown by Surgeon-General Cornish. One of the coldest winters known in Europe for years had failed to arrest or stamp it out, as was shown by the reappearance of the dread plague this summer. The untiring efforts of our American Government and local authorities had prevented its gaining a foothold among us. But how long has this preventable disease to be fought by nations not responsible for it? Why should a fanaticism of the Mohammedans of the East jeopardize the interests, health, and life of the whole world? There was no doubt that cholera was a reproachable cause of death that could be laid to the door of the British Government. After detailing the steps of the advance of cholera into the various points of

Europe last year, the author went into the subject of treatment. In Hamburg the best results had been obtained from the use of hot bottles with clysters of tannic acid and water and hypodermic injections of camphor. There was a very strong argument in favor of inoculation, in the fact that persons once affected by cholera were somewhat safe against it. As prevention was better than cure, the author was in favor of inoculation with the matter as prepared by Pasteur.

Dr. ERSKINE B. FULLERTON, of Columbus, Ohio, referring to the treatment of cholera, believed that he was the only man who had been successful in combating the disease with quinine. The facts and figures were given to prove that the disease treated in the penitentiary at Nashville, Tenn., in 1873, could have been nothing other or less than malignant Asiatic cholera, kept in check by the constant administration of quinine in sufficient doses. The speaker pointed out the fallacy of using the remedy hypodermically or by the unscientific intravenous injection. He believed that there was an identity between cholera and malarial disorders which accounted for the benefit from the administration of quinine. He also gave figures showing the impossible doses of other remedies necessary to equal in inhibitory effect forty grains of quinine. To reach the seat of the disease, the remedy must be given by the mouth. Fifteen grains of quinine were sufficient to inhibit the growth of the germ in about five quarts of fluid. With the rapid peristalsis of cholera, and the very small quantity of the remedy that would be lost through absorption, the currents being into and through the bowel, it was quite reasonable to suppose that even in the intestinal tube these experiments would hold good, and the quinine, instead of being absorbed by the stomach, would pass onward to the intestine where it was needed. When the remedy was given hypodermically it passed out rapidly by the kidneys and was lost to attack the disease, which was in the intestine. The speaker believed that the experiments of Sir Spencer Wells and Dr. E. A. Parkes, with their intravenous injections of quinine, resulting in a high rate of mortality, had done much to injure the cause of this drug. All authorities had agreed that quinine in almost all cases very shortly stopped the vomiting. The diarrhoea was usually checked within a few hours. Where the dose was sufficient, reaction promptly followed the cessation of the symptoms, there was no consecutive fever, and convalescence was rapid. It appeared from the records that doses of about ten grains every hour seemed usually to give better results than larger doses at longer intervals. In the fulminant cases the thing to do was to give the quinine more rapidly. In cases of obstinate vomiting enteroclysters of quinine, forty to sixty grains in two quarts of warm water, should be tried. There would be an inhibitory margin for four times the amount of fluid mentioned, and some of this might be got beyond the ileo-colic valve. A long list of tables was read showing the rate of mortality under different treatments during different epidemics. The recent Hamburg epidemic, under "mixed" treatment, had caused a mortality of 48.4 per cent. The author's report, gathered from the epidemic of 1873 and others of recent dates, under the quinine treatment, showed the remarkably low mortality of 4.8 per cent.

Some Medical Facts connected with the Discovery of America.—Dr. A. M. FERNANDEZ DE YBARRA, of New York, read a paper with this title. He said that the principal object of his paper was to state what he had been able to gather together from a lengthened correspondence of the probable disease that had caused the death of Christopher Columbus and his ailments during his voyages of discovery in America. Instead of mental impairment coming, as had always been said about the great discoverer, it was shown that his mental vigor had kept up until the very last. His great suffering from chronic

articular rheumatism, taken with the facts of physical incapacity from that cause and his many bitter disappointments, had rendered him morose and irritable. But if these obstacles had been removed and Columbus could have carried out his desires, the world would never have heard of insanity in connection with him.

Amœbic Dysentery.—Dr. H. A. WEST, of Galveston, Texas, read a paper on this subject. He said that the question of amœbic dysentery was of practical importance in consequence of the diversity of opinion in regard to the definition, varieties, and ætiology of dysentery; and more especially the non-recognition by the general medical profession of the causal relations of the *Amœba coli* in the production of dysentery and the wide dissemination and frequent occurrence of this form of the disease. He called attention to the following points: 1. The importance of a correct definition of dysentery. It was not, as was usually taught, a morbid entity, consisting of an inflammation of the large intestine essentially the same in all forms and climates, varying only according to climatic and other modifying conditions. On the contrary, the term dysentery should only be used in a general sense to express a group of inflammations of the large intestine, partly of specific and partly of non-specific origin. 2. The adoption of the following classification would do much toward dissipating the existing confusion—viz., acute catarrhal, acute diphtheritic, amœbic, and secondary dysentery. 3. Amœbic dysentery was more widely disseminated and occurred with greater frequency than was generally supposed. 4. To emphasize the probable entrance of the amœba through impure drinking water. 5. To note the characteristic and uniform symptoms of this form of dysentery. 6. The essential chronicity and difficult cure depending upon the character and location of the lesions. 7. The necessity of combating the excessive anæmia and wasting by the use of a more liberal diet than was generally prescribed. 8. To urge the importance of cleansing and antiseptic irrigations as a rational method of reaching and destroying the amœba and stimulating the intestinal ulcers to heal. 9. To note the fact that, while solutions of quinine were destructive to the amœba, injections of the same had failed to exercise any marked curative power. 10. The speaker's experience showed that mild injections of nitrate of silver (thirty grains to a quart of water), with the occasional administration of salines and large doses of bismuth and salol, constituted the best treatment.

The details of seven cases illustrative of these points, treated in the John Sealy Hospital, Galveston, from October, 1892, to June 1, 1893, showed the comparative frequency of this form of dysentery in that locality. There were only two or three cases of catarrhal and none of diphtheritic or secondary forms admitted during that period. Two of the cases had originated upon the same steamship in Vera Cruz, and the fact strongly pointed to infection through the drinking water. One of the patients had acquired the disease while traveling through the Indian Territory and North Texas. One was from Arkansas, where he had lived for some time in the alluvial bottoms of the Mississippi and Red Rivers. Those two had also drank impure and stagnant water. The other three cases had originated in Galveston or its immediate vicinity, and no history of infected water could be obtained.

The symptoms were very uniform; though they might begin acutely, they would very soon become chronic, and were characterized by irregularity in the flux. The character and frequency of the stools alternated between improvement and relapse. The difficult cure and chronicity depended upon the nature of the lesions—viz., ulceration of different portions of the large intestine and sometimes of the ileum, with a disposition to infiltration and undermining of the mucous membrane.

affording a nidus for the development, growth, multiplication, and destructive work of the micro organisms. The nature of the disease was such as to produce very rapid anæmia and wasting. It was necessary to combat these results by the plentiful use of nitrogenous food. The character of the lesions gave the key to the most successful treatment, which consisted of thorough irrigation of the intestine—first, with simple warm water for cleansing purposes; secondly, with an antiseptic solution for destroying the organisms and stimulating the ulcers to heal.

Dr. GARDNER, of Indiana, related his experience with the class of cases described by Dr. West, and said that he had come to the conclusion that there existed an undoubted relationship between drinking water and amoebic dysentery.

Dr. WILLIAM OSLER, of Baltimore, thought that under different circumstances the symptoms of amoebic dysentery varied, and that they might approach those of typhoid fever, such as hæmorrhage, exhaustion, and death. He also thought that there was an association between that form of dysentery and hepatic abscess.

He had found in some acute cases the injection of quinine to be very beneficial, but as a general thing the nitrate of silver to be more reliable.

The Bacteriology of Dengue Fever.—Dr. J. W. McLAUGHLIN, of Austin, Texas, read a paper on this subject. The paper was a review of original investigations in the bacteriology of dengue fever which the author had made in 1885, during the last epidemic of that disease which visited the Southern States of North America. In addition, the author was now able to present for the first time photo-micrographic illustrations of the micrococcus which he had obtained from the blood of persons suffering with dengue fever. An inspection of the photo-micrographs reproduced revealed group arrangements of the micrococcus that were distinctive of the micro-organism of dengue fever and were not found in other pathogenic bacteria. The three photo-micrographs exhibited represented distinct and different group forms of the same coccus, which, however, bore a relationship to each other. They had been obtained from the same mounted preparation of jelly culture. As the same group forms were constantly found in other mounts, the conclusion that they represented development stages in the biological history of the micro-organism seemed well taken. And, furthermore, as this grouping had never been observed in other pathogenic bacteria, and was characteristic and distinctive of the culture of the micro-organism which had been obtained from the blood of the dengue-fever subject, the author felt justified in maintaining that it was intimately, if not causatively, associated with that disease.

Some remarkable results had been obtained by applying glacial acetic acid to cover-glass preparations of freshly drawn dengue blood. When these were examined with a dry one-sixth, or, better, with a one-twelfth oil-immersion objective, numerous ovoid cocci of a yellow-brown color were seen in the blood plasma. The blood-cells, which could be distinctly seen, were normal in appearance and numbers and did not contain any of the ovoid bodies. If such results were confirmed by future investigations they would be valuable for diagnostic purposes. In conclusion, the author said that, as the work had been done in 1885, and at that time the apparatus with which he had had to deal was more or less extemporized, he hoped that the imperfections of his work would not be too closely criticised. That there were many, he was sure, especially when viewed from the present advanced standpoint of bacteriology.

Dr. GARDNER was glad to find that an advance had been made in the pathology of dengue fever, and that to Dr. McLaughlin was due the honor of isolating the pathogenic germ. For his part, he had always been inclined to think that there

was an association between influenza and dengue fever. At any rate, if there was not a pathological relationship, there was certainly a marked clinical similarity.

Dr. West did not think that because dengue fever had some of the symptoms of influenza they were one and the same disease. There was no doubt in his mind that dengue fever had a distinctive pathogenesis. To the author of the paper great credit was due for his work in establishing a definite germ as a causative agent in dengue fever.

On the Culture of Anaerobic Bacteria.—Dr. F. G. NOVY, of Ann Arbor, Mich., read a paper with this title. The paper consisted of a brief *résumé* of the principles and methods employed in the culture of anaerobic germs. The methods were described under five headings: 1. Exclusion of oxygen. 2. Exhaustion of air. 3. Absorption of oxygen. 4. Displacement of oxygen. 5. Cultures in the presence of air. Hitherto examinations of micro-organisms of this class had been attended with such difficulty and expense that no great advance had been made in their study. The speaker exhibited an apparatus which he had had made in Germany, and which for simplicity could not be improved. It was a vacuum glass jar made large enough to hold several culture tubes. The apparatus permitted of the making of large serial cultures and the use of various culture media, whether solid or liquid, and also enabled streak cultures on agar and Esmarch roll tube cultures to be made. The usual sealing in a flame was discarded and replaced by a much more convenient procedure. The culture media employed for the growth of anaerobic bacteria were also discussed, and the value of peptone, glucose, and gelatin additions was carefully pointed out. The addition of litmus was shown to possess some valuable properties. Pure cultures of anaerobic bacteria could readily be obtained even in the presence of air with as much ease as ordinary aerobic cultures. The common anaerobic bacteria could be thus cultivated without any special apparatus, and such cultures furthermore possessed the advantage of retaining their vitality for a considerable length of time.

A New Anaerobic Bacillus of Malignant Œdema.—Dr. NOVY read a second paper with this title. He said that in several guinea-pigs which had died after injections of an impure milk nuclein solution, a marked œdematous condition had been observed, resembling, and even more pronounced than, that of malignant œdema. In the subcutaneous tissue, peritoneal exudate, heart-blood, spleen, liver, etc., had been found enormous numbers of long, slender bacilli. This organism was found to be anaerobic in character, and pure cultures possessed marked infections and extremely toxic properties, producing death in from twelve to thirty-six or forty eight hours, with the characteristic œdematous condition. White rats, white mice, rabbits, guinea pigs, and pigeons were all extremely sensitive to the poison. The organs and tissues of animals that had died after inoculation with pure cultures contained very few germs, and often none could be found, showing that the normal body was not a very good soil for the growth of the germ. By injecting certain chemical substances and cultures of common non-pathogenic bacteria at the same time with the virulent germ, this natural resistance of the body was altered, and as a result the germ developed in enormous numbers throughout the body. This new, highly pathogenic, anaerobic bacillus was motile and the flagella could be readily demonstrated by Löffler's method. In some of the cover-glass preparations made from animals colorless spirals could be observed. In cultures on certain media and under certain conditions there were found similar spirals which in reality were giant whips. These could be seen in hanging drops even with a dry objective. These abnormal flagella were exactly the same as those described by Löffler in connection with symptomatic anthrax, and their formation was

probably due to involution changes. The germ was readily stained with simple dyes and also by Gram's method. Spore formation had not been observed, but the germ itself was extremely resistant. It could be grown in vacuum, in hydrogen, in carbonic acid, in nitrogen, and even in illuminating gas.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Fifteenth Annual Congress, held in New York on Monday, Tuesday, and Wednesday, May 22, 23, and 24, 1893.

The President, Dr. MORRIS J. ASCH, of New York, in the Chair.

Diphtheria: its Prophylaxis and Treatment.—Dr. BEVERLEY ROBINSON, of New York, read a paper opening a discussion on this subject. (See page 148.)

Dr. J. C. MUEHLLER, of St. Louis: At the last meeting of the association I said something about house posting in the prophylaxis of diphtheria, and that remark gave rise to this proposed discussion. I expressed myself strongly in favor of posting houses, and Dr. Robinson was just as strongly opposed to it. He has, however, said nothing concerning the very point which last year gave birth to this discussion. Looking at the question from this point of view, I should like to relate a case or two of some interest, inasmuch as they have to do with the prophylaxis of diphtheria. In St. Louis a child was taken seriously ill and was attended by a homœopathic physician. It was a case of diphtheria, but, at the request of the members of the family, the physician did not post the house. Some three or four weeks afterward the child appeared on the street with a bandage about the throat. The children in the immediate neighborhood were very glad to see it again, and they interviewed it, etc. The child had a whistle which he allowed the child who lived in the next house to use. This second child contracted diphtheria on the fifth day and died. Three other children in the block, who, as was subsequently learned, also blew into the whistle, were attacked with the disease; all three recovered, one, however, with post-diphtheritic paralysis, which lasted for four or five months. Now, I maintain that had the first house been posted in accordance with the law, the mother of the second child, who is very punctilious, would not have permitted her child to play with the child that was convalescing from diphtheria. The contagion of diphtheria is very seldom portable, for if it were, the disease would be more common than it is in doctors' families. The following, however, is an interesting case, and illustrates that the contagion of the disease may be carried by the patient for three or four weeks after convalescence: An Indian child was taken with diphtheria in St. Louis, involving the nose, larynx, and pharynx. It recovered after intubation. I was the consulting physician. Dr. William Barker succeeded in saving this child's life. During the third week of convalescence the child was sent to the home of its parents in North Topeka. The parents had a little farm four miles from North Topeka. There was no diphtheria in Topeka—and certainly none in the country four miles from its suburb, North Topeka. This Indian child took with her a doll with which she had played during her illness. On the fourth day after her return home her sister, aged four years, was attacked with diphtheria, and died with that disease after five days. This goes to show the portability of the disease by the patient or its playthings. As Dr. Robinson said in his paper, the bacilli may be found in the throat five weeks after the membrane has disappeared.

Prophylaxis by means of disinfection has more reference to the children themselves than to their surroundings. I am perfectly in accord with Dr. Robinson that sulphur fumigations have no effect whatever in stemming the contagion. I have

seen houses fumigated in this way after the occurrence there of diphtheria, and two months afterward treated other cases of the disease in the same house. Even with the aid of vapor, sulphur fumigations can not prevent the recurrence of the disease in a house.

It is true that the attendants in the sick-room do sometimes acquire diphtheria. In one case two children had diphtheria and recovered, and their father, who had nursed them, was then attacked with it and died in three days. The personal prophylaxis of children consists, therefore, in not allowing them to associate with or go near any child within five or ten weeks after it has recovered from the disease. The condition of the soil, the condition of the throat, has everything to do with the question of whether a child shall become diphtheritic or not. The personal prophylaxis is very important. Children with good hygienic surroundings and whose mucous membranes are in a perfectly tonic condition seldom acquire diphtheria or any other contagious disease. Children with enlarged tonsils are the ones who usually contract the disease.

As to the attire of the physician who enters the sick-room, I do not think this point is of such great importance, as it has been proved that diphtheria is seldom carried by the doctor. Why then attire ourselves in this armor? I know of one physician who, when he enters the sick-room, always puts on a rain coat and a skull-cap and disinfects his hands afterward. He has a heavy moustache, but this he never disinfects or shampoos after leaving the room, which is not consistent with his other precautions, as I think the hairs are more likely than anything else to carry the contagion.

As to treatment: I wrote a paper about five years ago in which I stated that, as far as my experience went, there were two things to be attended to. One was to sterilize the upper air passages, and the other was to maintain the nutrition of the child. Beyond these two measures I had very little faith in anything else, including drugs. I maintained then that it was a mistake to irritate the child by constantly cleaning the throat. It makes a great difference whether the child is a well-disciplined or a spoiled child. If you have to deal with a child that shrinks and fights when you ask it to show its tongue, there is not much use in direct personal disinfection, because the constant struggle causes more harm than you can do good by attempting to sterilize the upper air passages. I showed that the gentlest way of doing this was by means of a common household syringe. This is done by removing the hard rubber point from the syringe, have the child lie on one side, introduce the point of the syringe into the pharynx, and wash as hard as you please; not a single drop enters the larynx. It is prevented by the reflex movement of the base of the tongue. I also introduced a nasal syringe for the purpose of cleaning the nares in diphtheria; the opening of this syringe was very large, so that it was impossible to throw a violent stream. I endeavored to show the importance of disinfecting the posterior nares, on account of the plentiful distribution of the lymphatic tissues in that location, and the consequent great danger of the rapid absorption of ptomaines. This can not be done by means of sprays or the household syringe, because of the contraction of the soft palate. I prefer the compound solution of iodine, variously diluted, to any other remedy for cleansing purposes. I desire to pay tribute to Dr. Park, of New York, for his grand investigations of this subject. He informs us that it takes fourteen hours to positively determine the presence or absence of the Klebs-Loeffler bacilli in the exudate. It seems to me that until the diagnosis is positive, all cases at all suspicious should be treated as diphtheria. If it proves to be something else, we have done no harm.

(To be continued.)

Book Notices.

Sciatic Neuritis: its Pathology and Treatment. By ROBERT SIMPSON, L. R. C. P., L. R. C. S. Bristol: John Wright & Co., 1893. Pp. 46. [Price, 1s.]

THIS little brochure reviews the history of sciatica, giving an excellent *résumé* of the pathology of the disease, and the author urges the use of massage in its treatment, not to supersede appropriate medicinal treatment, but as an adjunct in arousing the diseased nerve structure to normal functional activity.

Circumcision: its Advantages and how to Perform it. By M. CLIFFORD, L. R. C. P. Lond., M. R. C. S. Eng. London: J. & A. Churchill, 1893. Pp. 23.

THE author states that he brings out this pamphlet in order to present the details of the methods he adopts in performing circumcision. We do not believe that it is either well known or accepted by even a minority of the profession that a long prepuce causes the catalogue of ills the author notes; in fact, many of these conditions, especially masturbation and reflex neuroses, are observed in the children of Jews, who have been deprived of their foreskins. The author advocates the familiar operation of removal of the prepuce, with a shield to guard the glans, the incision being parallel with the line of the corona glandis; certainly not a new operation.

BOOKS, ETC., RECEIVED.

A Treatise on Ophthalmology for the General Practitioner. By Adolf Alt, M. D. Second Edition, revised and enlarged. With One Hundred and Forty Illustrations. St. Louis: J. H. Chambers & Co., 1893. Pp. xv-330. [Price, \$3.50.]

Health's Practical Anatomy: a Manual of Dissections. Eighth Edition. Edited by William Anderson, F. R. C. S., Surgeon and Lecturer on Anatomy at St. Thomas's Hospital, etc. With Three Hundred and Twenty nine Engravings on Wood. Philadelphia: P. Blakiston, Son, & Co., 1893. Pp. xviii-744. [Price, \$5.]

The Clinical Uses of Prisms, and the Decentering of Lenses. By Ernest E. Maddox, M. D., formerly Syme Surgical Fellow, Edinburgh. Second Edition, revised and enlarged. Bristol: John Wright & Co., 1893. Pp. xi-170. [Price, 4s. 6d.]

Sciatic Neuritis: its Pathology and Treatment. By Robert Simpson, L. R. C. P., L. R. C. S. Bristol: John Wright & Co., 1893. Pp. 46. [Price, 1s.]

The Use and Place of Caustics in the Treatment of Cancer. By Daniel Lewis, M. D., New York. [Reprinted from the *Annals of Surgery*.]

The Reconstruction of the Pelvic Structures in Woman. The Advantage derived from the Use of the Buried Tendon Suture. By Henry O. Marcy, M. D., Boston. [Reprinted from the *Transactions of the American Association of Obstetricians and Gynecologists*.]

Analysis of One Hundred and Thirty-three Cases of Hernia operated upon for the Purpose of Radical Cure. By Henry O. Marcy, M. D., Boston. [Reprinted from the *Journal of the American Medical Association*.]

Inguinal Hernia in the Male. By Henry O. Marcy, M. D., Boston. [Reprinted from the *Transactions of the Southern Surgical and Gynecological Association*.]

Enteroptosis, or Glenard's Disease. By Max Einhorn, M. D., New York. [Reprinted from the *Post-graduate*.]

Dietetics in Diseases of the Stomach. By Max Einhorn, M. D., New York. [Reprinted from the *Medical Record*.]

My Recent Urethral Work—Catheterization of the Ureters. By Howard A. Kelly, M. D., Baltimore. [Reprinted from the *Annals of Gynecology and Pædiatry*.]

Twenty-ninth Report of the Trustees of the Boston City Hospital: with Report of the Superintendent, the Medical and Surgical Statistics, Rules for Admissions and Discharges, Prospectus of Training School for Nurses, Rules for the Convalescent Home, etc. For the Year, February 1, 1892, to January 31, 1893.

Du traitement des abcès du sinus maxillaire. Par le Dr. A. Cartaz de Paris. [Extrait de la *Revue internat. de rhinologie*, etc.]

A Dictionary of Medical Science: containing a Full Explanation of the Various Subjects and Terms of Anatomy, Physiology, Medical Chemistry, Pharmacy, Pharmacology, Therapeutics, Medicine, Hygiene, Dietetics, Pathology, Bacteriology, Surgery, Ophthalmology, Otology, Laryngology, Dermatology, Gynecology, Olistetrics, Pædiatrics, Medical Jurisprudence, Dentistry, etc. By Robley Dunglison, M. D., LL. D., late Professor of the Institutes of Medicine and Medical Jurisprudence in the Jefferson Medical College of Philadelphia. Twenty-first Edition, thoroughly revised and greatly enlarged, with the Pronunciation, Accentuation, and Derivation of the Terms, by Richard J. Dunglison, A. M., M. D. Philadelphia: Lea Brothers & Co., 1893. Pp. xi-1181.

Chloroma and its Relation to Leukæmia. By George Dock, M. D., Ann Arbor, Mich. [Reprinted from the *American Journal of the Medical Sciences*.]

Report of the Trustees of the Newport Hospital, presented to the Corporation at its Twentieth Annual Meeting, July 11, 1893.

Concentrated Rays of the Sun (Solar Cautey) as a Remedial Agent. By O. V. Thayer, M. D., San Francisco. [Reprinted from the *Pacific Medical Journal*.]

Miscellany.

Mr. Ernest Hart on the Profession, the Public, and the Code.—Mr. Hart has kindly supplied us with advance proof of a stenographic abstract of the address delivered by him at one of the general meetings of the First Pan-American Medical Congress. It reads as follows:

Sir Astley Cooper, one of the greatest surgeons and most accomplished gentlemen of the last generation, was in the habit of addressing every candidate for membership of the Royal College of Surgeons of England, of which he was president, somewhat in the following words: "Gentlemen, you are about to enter on a noble and difficult profession; your success in it depends on three things: First, on a good and thorough knowledge of your profession; second, on an industrious discharge of its duties; and third, on the preservation of your moral character. Without the first—knowledge—no one can wish you to succeed; without the second—industry—you can not succeed; and without the third, even if you do succeed, success can bring you no happiness." Those words might form a very adequate summary text for guidance of the conduct of all medical men. And it might conceivably be asked whether there is any necessity for a more detailed and elaborate code. Indeed, it practically has been asked, and there are large questions involved in the decision. On the other hand, it has, from time to time, lately, in our country been found necessary to re-enforce and strengthen our code by additional declarations, and I think to some extent

in yours; the need for a stringent upholding and development of the code has also become a question of the day. I think it is clear that if ever there were such necessity, at no time could it be stronger than at the present moment. For under the stress of the modern social development, under pressure of the modern temptation for advertising and the severity of competition, in view of the arts of those who make advertisement a business and a profit; in presence of the temptations held out to draw medical men from the ancient paths of modesty and self-effacement, there is now stronger reason than ever to fortify ourselves against those growing and innumerable seductions by a code so exact, so far reaching, that the physician need never be in doubt as to what is his duty in any complication, or in the face of any doubtful case in which he may be inclined to give himself the benefit of the doubt.

But, first of all, I want to elaborate the view that our rules of medical etiquette stand upon a logical and strong basis, and that their strict enforcement is for the benefit of the public, at least as much, if not even more, than for the benefit of the profession. Medical etiquette has been sneered at by shallow cynicism as mere trades unionism. It is, on the contrary, a self-denying code which is made in the interests of pure morality, and for the benefit of the public far more than for the interests of the profession. This allegation of trades unionism is the converse of that of intility, which those who are prone to call themselves of the younger school allege; but not even the youngest of us, as you know, are infallible, and in this matter it is the youngest who are most likely to go wrong. They proclaim themselves liberals. Is it, however, in some cases, the liberalism of Gallio? Let us look at this matter from the largest and most liberal standpoint. Let us begin by comparing our code with the standards of the legal profession.

My distinguished friend, Sir Edward Clark, lately the Solicitor General of England, in writing to me on the subject, recently said the essence of the matter might be summed up in a very few words: "Every lawyer ought to be a gentleman, and ought to do only what is right and honest; if he does not, other men ought to have nothing to do with him." Notice that "if he does not, other men should have nothing to do with him." That position of the bar should be strengthened by this, that the etiquette of the bar is absolutely in the hands of the bar circuits and attorney general, and that of the solicitors in the hands of the Incorporated Law Society; so that any solicitor who is guilty of an offense, whether as a lawyer or as a gentleman, can be, and from time to time is, not only temporarily suspended, but deprived of the right to practice at all. In a case tried last July in England, a solicitor in a certain town had been the proprietor of a house used for an immoral purpose, of which he received the rent. That was considered a stain upon his character as a gentleman, and for that he was suspended from the roll and excluded from practice. So that we have at least the example of the legal profession, who have a code even stricter than ours, in insisting upon a high standard of honorable conduct in the profession.

Legal etiquette prescribes certain technical acts which a lawyer must not do. An eminent American lawyer, whom I had the pleasure of meeting, mentioned to me, for example, that he may not conduct a "speculative suit"—that is, he may not conduct a suit in which his pay is to depend on the success of the suit—a palpable restriction on his liberty. Liberty is a blessed word, but compulsion is, under certain circumstances, often a more blessed word. The reason for this rule is that if a lawyer undertakes such a suit he becomes personally and financially interested in the result, and may be tempted not to give the Court all the aid which is his duty, or may in the end lose the relations of harmony and respect which are indispensa-

ble between the Court and the lawyers, who are officers of the Court and are bound to help Justice to duly balance its scale.

In the same way "champerty" is a legal offense. So, too, no respectable lawyer will give separate advice upon a case which is already in the hands of a colleague. As between advocate and advocate, harmony, courtesy, and the forms of friendship must prevail; and at any time they must in the interest of the client be able to come together and to seize the earliest opportunity of avoiding litigation by compromise or mutual settlement, where it is possible and right. The etiquette of the bar is very strict, and is closely observed.

Legal etiquette is, like medical etiquette, a code of honor and of duty by which the public benefit; and those who depart from it or deride it—"legal shysters" I think they are called in the United States—are not, any more than medical quacks, those of whom their country or their profession have most reason to be proud.

I will pass at once to the consideration of our code of medical etiquette. I will ask you to consider whether you are of the opinion that it is safe or wise to cast aside the precedents of past experience and to substitute individual judgment for settled rules. If man were a purely abstract and perfectly moral intelligence, no doubt few words would suffice to legislate for his daily needs. Enough to say, "Do unto others as ye would they should do unto you."

But medical men are not pure creatures of perfect and abstract morality any more than other men. They have, indeed, certain advantages from the outset. From the very beginning of their professional life it is impressed upon them by their teachers that their profession is a *mission and not a trade*; a mission involving frequent self-sacrifice and a steadfast regard for interests other than their own. In this they are greatly helped by the force of precedent, by the example of those around them, and of the leaders whom they most respect. But even these are inadequate. Without the aid of the written as of the unwritten law, even the best of men are apt to decide *wrongly in their own favor* on a doubtful question of ethics, and often in matters and cases where there are settled instructions in the code which would guide them rightly.

Let me read to you a few of the rules of our College of Physicians, which command with us a universal adhesion and respect. I do so only as an example of the conclusions to which many years of observation of the impingement of the forces of modern life on professional duty have led some of our wisest heads. I will refer only to a few as follows:

"No candidate shall be admitted to examination who refuses to make known, when so required by the president and censors, the nature and composition of any remedy he uses."

"That the practice of medical authors frequently advertising their own works in the non-medical journals, and especially with the addition of laudatory extracts from reviews, is not only derogatory to the authors themselves, but is also injurious to the higher interests of the profession."

Again, "No fellow, member, or licentiate of the college shall officiously, or under color of a benevolent purpose, offer medical aid to, or prescribe for, any patient whom he knows to be under the care of another doctor."

A further rule prescribes that no physician shall himself assume any special designation of therapeutic method, such as homœopath, electropath, hydropath, or countenance those who do so.

Again, "A physician shall have no interest in a secret medicine, and that he shall always, when called upon by the college, disclose every part of the composition of his medicines."

"If it shall at any time hereafter appear, or be made known

to the president or censors, that any fellow or member of the college has obtained admission into the college or that any licentiate of the college has obtained the license of the college by fraud, false statement, or imposition, or that any fellow, member, or licentiate has been guilty of any great crime or public immorality, *or has acted in any respect in a dishonorable or unprofessional manner*, or has violated any statute, by-law, or regulation of the college, relating to fellows, members, or licentiates, as the case may be, the president and censors may call the fellow, member, or licentiate so offending before them, and having investigated the case, may admonish or reprimand, or inflict a fine; or if they deem the case of sufficient importance, may report the case to the college, and thereupon a majority of two thirds may declare such fellow or member or licentiate to be no longer a fellow, member, or licentiate, as the case may be, and his name shall be expunged."

Let us consider now those restrictions which operate to forbid a medical practitioner to consult with "homeopaths," and of which the wisdom has been by some disputed. We do not believe, and we can not appreciate the medical capacity or fitness to undertake the treatment of disease of those who hold that drugs which, given internally, will produce certain symptoms of disease are the appropriate remedies for those maladies. For instance, medicines which produce skin reddening for erysipelas; leucorrhoea for leucorrhoea; syphiline for syphilis. We do not agree that all chronic maladies arise from syphilis, sycoosis, or itch, and that medicines act with an intensity proportionate to the infinite diminution of the dose, or that there is any utility in prescribing, in accordance with these principles, say a decillionth of a grain, when we all know that a dose so small, if taken by every being on the globe once a minute would not finish the grain in thousands of years. Nor, again, do we believe that the activity of medicine increases in the ratio of the number of shakes given to the vessel containing it. We hold that we have nothing in common with those who assume to base their practice and theory on this kind of therapeutics. Being well assured that these methods and this theory are absolutely delusive, the negation of reason and the acme of folly, it would be useless, deceptive, and contrary to good faith and the public interest that we should pretend to consult with those who profess them and who take a designation derived from them, and to cover with the respectability of logical science what they are pleased to term their system of treatment. Faith curing it may be, but in that too we can take no part under false pretenses.

But then it is said, What if the physician or surgeon of good standing is only called in by the homeopath to assist in diagnosing the nature, the stage, the complications, or name of the disease? Ought he not to give this help for the patient's sake? The answer is, the physician is a healer; not a reader of riddles nor a conner of conundrums. He is there not to give a name to symptoms or pathological conditions, but to heal the patient; and if he knows that his solution of the riddle is not to be followed by a method of treatment which he considers capable of attaining that result, he would be infamously wrong, and he is always wrong when he gives the cover of his accepted position, of his recognized ability, and his professional sanction, to what becomes under such circumstances a dangerous farce or a deliberate fraud. The riddle is read, but the patient is none the better.

But it is said, May a regular medical practitioner not be called in to perform a difficult surgical operation? If a surgical operation meant only cutting, sawing, and sewing, it would be a plausible excuse for the surgeon accepting the responsibility of acting as sawbones to a quack. But there is no surgical operation which does not, in its preliminary stages, and may not

in its various phases and sequels, require concomitant medical consideration and treatment, or in which septic, constitutional, or accidental complications may not arise. The surgeon can not honorably, in the interest of his client, divest himself of the responsibility for the wise and faithful treatment of these as an essential part of his operative interference.

I have used the word quack. It is a word often used now in too restricted a sense. This is Dr. Johnson's definition of a quack: "A boasted pretender to arts which he does not understand; a vain, boasting pretender to physic, one who proclaims his own medical abilities in public places; an artful, tricking practitioner in physics." This strikes at the root of the matter now as then. Observe, here is no distinction between those who have degrees and those who have not. The great lexicographer makes no distinction; neither do I.

The essential note of the quack is love of advertisement. The public "places" of Dr. Johnson's time were the coffee-houses; they are now the newspapers. Now, what are the ways in which the diplomaed quacks adopt the methods and become the imitator, the rival, the accomplice of the undiplomaed? You may know them by their works. They are the gentlemen who put themselves forward to be interviewed, and are the sham Jupiters and willing Mercuries of the newspaper world. They confide to the ubiquitous reporter what is their opinion of the last new bacillus, the last new antitoxine, or invite reporters to their amphitheatre and hospital ward. All this is only an outcome of the venal desire for advertisement. They are the gentlemen who, if they have the good fortune to attend a prize fighter or a ballet girl, or the ruler of a State, are not slow to disclose the secrets of the sick-room, and all for the public good.

Now, in the venerated oath of Hippocrates, which is the foundation of our code of to-day, the disciple swears to impart the knowledge of his art to others according to the law of medicine, and to share with his colleagues by precept and every other mode of instruction all that he knows. He further binds himself that he will have no medical secret, that he will practice his art and pass his life with purity and holiness, that he will abstain from every voluntary act of mischief and corruption, and that *whatever in connection with his professional practice he sees or hears in the life of men which ought not to be spoken of abroad he will not divulge*. "While I continue to keep this oath unviolated may it be granted to me to enjoy life and the practice of the art respected by all men and in all times. But should I violate this oath may the reverse be my lot."

This is the spirit of the modern British code, and I know well it is yours also.

We have dwelt as long as time will allow on the considerations of public utility and professional duty which oppose consultations with homeopaths and their congeners; nor can I stay long to discuss the prohibition of open advertisement. The advertisement in the lay press of medical books intended for the profession; the submitting of technical books to review; the public criticism of the treatment of any disease or person; the thousand and one acts, in fact, by which the advertising surgeon physician seeks to gain the ear and favor of the public by means of notoriety or self-proclamation in place of hard honest work, real professional worth, and the judgment of those whose knowledge makes them alone competent to judge. Self-advertisement is the note of the quack. It is as dangerous to the public as hateful to the profession, for it misleads the masses by substituting easily purchased notoriety for merit, and covering by loud talk and bombast and plausible pretenses the emptiness of the shallow pretender. It covers also with a pseudo-respectability the venal corruption by which whole columns and pages

of reading matter of the newspaper are very frequently devoted to quack nostrums and "treatments"—save the mark—often of the most fantastic, false, and dangerous character. It destroys the landmarks of honor and reticence, when successive numbers of the daily and weekly papers are found the lucubrations of these pests of society, and, alongside of them, the interviews, the explanations, and the descriptive narratives put forth for the public good by reputable physicians, *à propos de lottes*, but hardly-veiled self-advertisement.

It is, however, only fair that the physician should have notice of the offense or its penalties, and that this salve which he puts to his conscience should be rubbed off. Hence the value of "A Code." We have seen that the medical man is prohibited from deriving any profit directly or indirectly from any medicine which he uses or recommends, and from tampering, however remotely, with secret medicines. If this were merely an arbitrary rule, if it were not at least as much for the benefit of the public as well as for the practitioner, there might be ground for calling it in question. But it is a rule of the highest public import.

That a healer, whose judgment in prescribing should be clear and unbiased, should possess and profit by a secret remedy is as obvious a source of public peril as it is a heinous offense against professional morality. Every physician has a traditional and immemorial right to expect from, and he is bound to give to, his fellow-practitioners every possible aid and assistance in the treatment of disease and in the healing of the sick. He has received such knowledge from his predecessors; he daily and continually receives it from his colleagues and contemporaries, to whose knowledge and experience, and from the results of whose investigations (openly stated and submitted to critical discussion) he owes the great bulk of his knowledge and of his ability to practice at all.

A new method of treatment, a new drug, or a new dogma in medicine is like a new doctrine or a dogma in theology. The one is as much a means of physical salvation as the other is of spiritual salvation. The man who keeps either of them to himself, as a profitable secret for his own mean gain, is a traitor to his profession; he is also a traitor to humanity, and he is false to his mission. It is fitting that the code should provide for such cases and that the penal clause should not remain a dead letter.

But it is sometimes suggested that the usefulness of the "secret" drug may be so great as to overpower and outweigh morality, and call for its prescription. I put it to you all, Is there any foundation for such an assumption in the whole history of medicine? In the whole history of the past can we recall any example of a secret medicine which had aught but the most insignificant value, or could not easily be replaced? We may take even the most famous, such as the famous remedy of Mr. Stephen, for dissolving stone in the bladder, for the divulging of which eminent men petitioned Parliament for a grant of £5,000. It was granted, and what do we read of the remedy when divulged? That it consisted of calcined eggshells or of lime obtained by a filthy and obscene process. Naturally, and like *all* secret remedies when divulged, it ceased to cure. Hartley—the famous Dr. Hartley—one of the most strenuous supporters of the grant, died of stone in the bladder after taking two hundred pounds of the remedy. In our day there is no such thing as a secret remedy in the true, or in any other than the trade meaning of the word. We doctors know the composition of all of them. They are secret only to the gullible public, to whom they are to be sold. Pain annihilators, blood-purifiers, vegetable and animal extracts, botanical nostrums, invigorators, electric belts, amulets and chains, Asiatic, African electrical pills and phials, "green, blue, and yel-

low electricity"—there is nothing secret about them. When examined in our private or public laboratories they are all found to be commonplace in composition, or if they have anything not well worn in use, it is merely the name of some indifferent or trivial matter—Indian grass or African leaf added, most often, and chiefly for the sake of novelty. These secrets are trade devices, with which we are not concerned. Let us visit those physicians who dabble in them with the severity of the code. I don't think that is asking more than is due to the honor of the professional body and the welfare of the public.

In respect then of secret medicines, at least, the world has up to this date lost nothing by the stern and scornful disapproval with which the medical profession regards these tricky nostrums, and by the punishment with which they visit, and always ought to visit, those who sell the honor of their calling and the free communication of medical knowledge which is the birthright of mankind for some mess of commercial pottage.

Finally, I will say a word or two of what is known as the etiquette of consultation. The patient, it is said, and is said cogently, has the right to determine whom he shall consult and to change his medical adviser if he desires so to do. No one will dispute that. But, like other rights, it is limited by the legitimate claims of others; and a medical practitioner may justly object if he shall be, without explanation or courtesy, superseded in attending on a case. In such event, moreover, the superseding practitioner is morally and ethically bound to take due care that the same courtesy and respect which he individually would expect to receive be paid to his discarded colleague, not only by himself, but by those who have professionally consulted him.

Every day cases of this kind occur; few days pass without bringing to me some complicated question arising out of them. The pages of our *British Medical Journal* are full of such questions. Very often, all I have to do is to say, See Code, page so and so, section so and so, and that decides both the practice and the principle. Probably if that is the case with us, it might occur here also, and not less frequently. Of one case I became cognizant here only the other day. An eminent doctor in a capital city of the United States of America was called in, came and saw a patient severely ill, said he would return; when the family physician returned in the evening he was told, "But you are not any longer in charge; Dr. so and so has charge of the case." He said: "But I don't understand, I was here this morning." "Well, it was the particular wish of — that the consulting physician whom you called in shall take charge, and you are not wanted." *Erit* family doctor.

Once more our College of Physicians explicitly directs that the physician called in to consultation by a brother practitioner shall not express directly to the patient his individual views and the conclusions at which he arrives, but that whatever he has to say shall be said after consultation with the practitioner, and through his mouth; that he shall behave with the utmost courtesy and forbearance to such practitioner, to whom shall be left all explanations and statements of the conclusion resulting from the consultation. Were it otherwise, were consultants authorized to supersede or to snub the family doctor, the public client would be the first to suffer, for anything which creates ill-will or unnecessary friction between consultant and family practitioner tends to limit the range and frequency of consultations. Therefore is it forbidden to the consultant called in subsequently to assume the sole charge of that patient, however he may be entreated to do so, or under whatever inducement. Were it otherwise, the attending or family physician could not call in a consultant without the fear being before his eyes of losing the charge of his patient. There would arise at once the temptation to limit and restrict consultations, and this

would be an impediment in the way of ascertaining the best means of cure by consultation. The strict observance of such rules and of the whole code as to consultations may sometimes be something of a personal trial to the patient, something of a personal loss to the consultant; but it is a rule which is of infinite importance to the public welfare.

The maintenance of a high standard of professional honor, the acceptance, adoption, and enforcement of a detailed code of professional etiquette, the agreement by all and the observance by every individual of the whole range of limitations and restriction, which are set up by that code and by the logical deductions from it—these things are, I contend, demonstrably as valuable to public welfare as for any professional interests concerned or supposed to be concerned.

I infer from the repeated and enthusiastic plaudits with which you have honored me that the opinions and conclusions which I have ventured to bring before you have agreed with your sentiments and are accepted by you sympathetically, and that you consider them opportune and proudly useful.

I have been encouraged by your continuous signs of general and warm approval to speak at greater length than I had intended. But there is yet much more to say. In thanking you now for this most gratifying ratification by the unbroken plaudits of this representative general meeting of the argument which I have ventured to state, it seems to me, of great importance to such progress or fair ethical development, I will only add that I shall be most happy to hear privately from any one who has doubts to solve or arguments to suggest, either for or against or in supplement of those which I have developed before you.

The Duty of the State to the Insane.—This may be summarized, according to an article by Dr. Andrew MacFarlane, of Albany, published in the October number of the *Popular Science Monthly*, as follows:

1. Separate treatment of curable and incurable under one medical executive.

2. For the curable cases, true hospital treatment, with all the medical skill, nursing, and care, regardless of expense, which the character of the case demands.

3. Simple, humane, custodial care at moderate expense, for the incurable.

The principle of separation of the recent from the chronic cases has been more or less adhered to in this State since the founding of the Utica Asylum in 1843. The recent State Care Act, however, makes no such provision, but directs that all the insane in each district be placed in one institution. It is true that \$4 25 a week is paid for each patient during the first three years against \$2.50 afterward, but this simply results in raising the general standard of care, at the same time failing to accomplish the purpose for which it is intended. There are many cases unmistakably incurable on admission, and for these only \$2.50 should be paid. On the other hand, no special provision being made for curable patients, they fail to receive any direct benefit from the larger amount paid for their maintenance. The time is therefore ripe for the establishment of an annex to each State hospital, which shall be conducted on the same plan as a general hospital, and in which curable patients can receive the energetic treatment demanded by their condition. A State hospital containing a thousand patients is now provided with a medical superintendent, five assistant physicians, and a woman physician. Not more than a hundred of the thousand patients—probably only sixty—can be regarded as suitable for the kind of treatment suggested. The remainder require kind custodial care only, under such medical supervision as could easily be given by two or three of the physicians.

The other physicians could thus be left free to devote themselves to the promising cases, and such patients could be placed in small, home-like cottages containing a separate room for each patient and a general sitting-room. The most rigid methods of physical examination should be employed when possible, including examinations of the blood and excretions and the use of the sphygmograph and ophthalmoscope; and baths of all kinds, electricity, and massage should be available as therapeutic measures. Special medical skill, experienced nurses, and means of mental diversion and occupation, such as are necessary in many cases, are already to be found at the State hospitals, and for this reason the plan suggested is much better than the establishment of separate hospitals for the acute insane and better than that of special wards or pavilions attached to general hospitals.

The nurses for service in the annex could be selected from those already employed in the hospital, and their number should be sufficient for every need. Associated with them should be several others who had received their training in general hospitals. The latter would be more likely to regard the cases from a purely medical standpoint, and thus a better spirit would be infused into the work of all.

The medical spirit would be more easily kept up among the physicians also. It is well known that, as matters are at present, physicians in hospitals for the insane are so handicapped by extraneous duties pertaining to the employment and diversion of the patients, interviewing their friends, and supervising the correspondence, that the medical spirit too often declines as the years go by. The British Medico-psychological Society, in discussing the best method of preventing this, concluded that the following conditions were desirable:

1. Classification—the curable from the incurable.
2. Hospital treatment for the curable.
3. Training for the attendants.
4. More physicians, and a rearrangement of duties.

The truest economy would also be consulted in thus making a vigorous effort to restore the curable patients to active life. They come from the strong, productive classes, often but temporarily overcome by ill-health or care. Those classed as incurable, on the other hand, are often mental incapables to start with, the victims of degeneracy in their ancestors, the last step before the extinction of the family. The average duration of life of the chronic insane is twelve years, and the cost of maintenance of each about five thousand dollars. To prevent as many as possible from lapsing into incurability becomes, therefore, the truest economy.

The cost for each patient in the annex proposed would certainly not be over ten dollars a week. If eighty of the thousand patients were thus provided for, and the remaining nine hundred and twenty cost three dollars a week each, the total weekly cost would be three thousand five hundred and sixty dollars. Under the present arrangement the average weekly cost for each patient is three dollars and fifty cents, or three thousand five hundred dollars for a thousand. The difference in expense is, therefore, very slight.

The evil effects arising from associating the recent subjects of insanity with the chronic are well known. The derisive remarks of the latter, their delusions, their offensive words and actions, and the possibility of a similar fate and long detention, add a horror to the situation which can be barely imagined, and serve to strengthen delusions and intensify morbid fancies by giving them an air of reality. The plan proposed would do away with these conditions. Moreover, it is by no means a theoretical suggestion only, as it is already in practical operation in Strassburg and Heidelberg and is contemplated in Scotland.

Original Communications.

REMARKS ON FERMENTATIVE DYSPESIA.*

By AUSTIN FLINT, M. D., LL. D.,

PROFESSOR OF PHYSIOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE,
NEW YORK; VISITING PHYSICIAN TO BELLEVUE HOSPITAL.

THERE are few diseases that present greater difficulties in the way of treatment and of permanent cure than what may be termed functional dyspepsia. In using the term functional dyspepsia I wish to be understood as meaning difficulty in digestion unconnected with ascertainable lesions of the digestive organs or of the alimentary tract, and not complicated with serious organic disease of other parts. While certain alterations may exist in the digestive organs, they are temporary, at least when the disease is not of long standing, and they must disappear in cases of permanent relief. Almost all cases of dyspepsia of long standing are accompanied with more or less mental and moral disturbance, even though the periods of pain or discomfort may not be very long. These nervous symptoms I do not propose to describe. They are protean in their character and manifestations, often relieved or mitigated by moral influences, such as change of scene or occupation, without much actual improvement in digestion. They almost invariably disappear as the normal digestive processes are restored. The long-standing "peripatetic" cases, with which physicians are unhappily too familiar, have been prominent among the unsatisfactory and discouraging experiences in general practice. Such cases usually are treated with but little expectation of permanent relief, and the most satisfactory result usually to be expected has been temporary improvement by means of palliatives, and a life rendered more or less miserable by a real or fancied necessity of constant attention to diet and general hygiene. It is in precisely such cases as these—unconnected with gross excesses or indiscretions in diet, and especially with the abuse of alcoholic beverages or narcotics—that modern medicinal therapeutics seems likely to produce such results as will render the treatment of fermentative dyspepsia of a purely functional character almost as certain and satisfactory as that of any acute trivial disorder.

Flatulence is a very common attendant of functional dyspepsia. This condition may be more or less pronounced, and there are great variations in the degree to which it is tolerated by different individuals. The discomfort and distress which accompany flatulence may amount to actual pain, which is sometimes, though rarely, intense; but when pain is habitual, remedies directed to its prompt relief are merely palliative and usually do actual harm in the end. This remark is especially applicable to all forms of opiates, whether administered by the mouth or by subcutaneous injection. Contrary to the popular and, to a certain extent, the professional notion, I must apply this remark as well to the various pepsins, pancreatins *et id genus omne*, so commonly prescribed. I have

fairly full records and histories of a score or more of what may be called peripatetic cases of dyspepsia of several years' standing which have been subjected to nearly every variety of routine treatment, and these constitute but a small proportion of the cases that have come under my observation. I have yet to see, however, a single case in which any of the pepsins, pancreatins, or the physiologically absurd combinations of pepsin and pancreatin logically seemed to have produced any benefit, even of a temporary character. In certain cases in which they have appeared to act favorably as palliatives, careful inquiry has almost invariably shown an attention to diet and hygiene during their administration to which their apparently favorable effects have been fairly attributable. If this statement is even in a measure correct, it is most important that the fact should be recognized and appreciated, in view of the gratuitous instruction in the physiology of digestion and the pathology and therapeutics of dyspepsia offered so freely to physicians in the advertising pages of medical journals and in circulars by pharmaceutical manufacturers and even meat packers, and indiscreetly indorsed by members of the profession. Of late years my opinions have not permitted me to extend my experience in pepsins, etc.; but the histories of previous treatment in cases that have come under my observation, as well as physiological considerations, have convinced me that agents intended to supply an assumed deficiency of digestive enzymes are absolutely inert. I do not wish, however, to be understood as including in this condemnation the use of foods partially digested, or peptonized, undoubtedly valuable in many cases.

This subject, to my mind, is so important that it seems proper to give my reasons for the decided opinion just expressed:

Digestion is one of the most complex of the physiological processes, and even now it is but imperfectly understood. Concerning certain facts, however, there can be no doubt. It is well known to physiologists that a combined as well as a successive action of the digestive fluids is essential to normal digestion. If the food is imperfectly masticated and insalivated, especially the latter, digestion becomes difficult. It is essential not only that the saliva should exert its own chemical and mechanical action, but that it should become gradually mixed with the secretions of the stomach, and that the gastric juice should as gradually be mixed with the food, the pepsinogen being transformed as it is discharged from the peptic cells into pepsin by the action of the hydrochloric acid produced by its peculiar cells. Assuming, even, that a few grains of what is called pepsin, extracted from a pig's stomach and dried, will have the same action in the human stomach that it has on minced food in a test tube, it is by no means certain that the discomfort and distress which are sometimes observed soon after taking food are due to deficiency of pepsin. As a rule, these symptoms are produced by the undue formation of gases, which artificial pepsin is not known to have any power to control. Normally the gases of the stomach do not exist in large quantity, and probably are derived mainly from the air which is incorporated with the food in mastication, an evidence of which is the presence of a con-

* Read before the New York State Medical Association, October 12, 1893.

siderable proportion of oxygen, which is not found in other portions of the alimentary tract. When gas is formed in the stomach, it is probably due to the action of micro-organisms, and these organized ferments take no part in digestion.

It is almost inconceivable that artificially extracted digestive enzymes can find their way into the small intestine in such a condition as to exert any action in digestion. The so-called pancreatin has no existence, the enzymes produced by the pancreas being trypsin, amylopsin, and steapsin. Intestinal digestion, also, is an alkaline process; and it has been abundantly shown by experiment that it can not go on with sufficient efficiency to support life in the absence of the action of the intestinal juice, the composition of which is unknown, and of the bile, the action of which has never been clearly understood and defined. Life, indeed, can not be maintained in the absence of either the bile or the intestinal juice alone.

Gases are much more abundant in the small intestine than in the stomach; and a certain quantity of gas is essential to the proper movements of the alimentary mass under intestinal peristaltic action. The composition of the gas in the small intestine—consisting, as it does, of carbon dioxide, pure hydrogen, and nitrogen in variable proportions—shows that it is in greatest part derived from the food, even if it be admitted that a certain proportion of the carbon dioxide may be evolved from the blood. When gases are produced in excessive quantity in the small intestine, the action of micro-organisms is probably involved. It is not pretended that the so-called pancreatin has any influence in modifying or restraining this action.

In cases of functional dyspepsia it is by no means invariable that the body is badly nourished, unless the diet is greatly restricted. Many dyspeptics have an appearance of perfect health. While digestion may be slow, labored, and attended with great discomfort and even actual pain, the processes may be efficient and complete, and general nutrition may be perfect. Although such cases are exceptional, they are not uncommon. It is seldom observed, however, that a strict diet called, perhaps, antidyspeptic secures immunity against dyspepsia, although it is desirable and useful to avoid notoriously indigestible articles and those which, in individual cases, have been found to occasion distress.

In my opinion it is seldom the case that undue fermentation in the alimentary mass begins in the intestinal canal. It usually occurs first in the stomach and is continued in the small intestine. In the exceptional cases in which its origin is intestinal there is usually a deficiency of bile, and more or less active diarrhoea is present. In the great majority of cases, however, constipation is fully as common as diarrhoea, and sometimes the bowels are regular. When there is no gastric flatulence, when the digestive discomfort begins two or three hours after the taking of food, and when diarrhoea with flatus is present, it is probable that the fermentation is purely intestinal and that it continues to an abnormal degree after the residue of food has passed into the large intestine. In all cases it is important to regulate the action of the bowels, either by laxatives or by

agents that have the opposite effect. I have been lately in the habit of using Villacabras water as a laxative when constipation is obstinate. By carefully regulating the dose of this water according to the effects observed in individual cases, I have found it act most satisfactorily. Using it for any considerable time, the dose, as well as the frequency of its administration, may be diminished rather than increased, and the dejections are usually easy and painless. I give before breakfast enough to produce two or three evacuations; and for two or three days after a daily movement follows. It may then be repeated if necessary and given as required. A very important point in the treatment of dyspepsia with constipation is to see that the patient acquires the habit of soliciting, without great effort, a movement of the bowels every morning at a fixed hour, resisting a desire for defecation at other times. Attention to this will sometimes regulate the bowels without the use of laxatives. In cases of undue looseness of the bowels, the remedies administered with the object of restricting fermentation will often suffice. Opium or its derivatives should never be used unless imperatively demanded by intense pain.

My main object in writing this paper is to call attention to the value of certain modern additions to the materia medica that act as antifermentatives. For many years the late Dr. Austin Flint was in the habit of using salicin in doses of about ten grains before each meal, often with remarkable success. I have used this remedy very largely and have frequently found it of great benefit; but I have lately employed other agents which seem to be much more efficient.

In nearly every case of functional dyspepsia that has come under my observation within the last ten months I have begun the treatment by giving five grains of bismuth subgallate, either before or after each meal. In some cases it seems to act more favorably when given before meals, and in others its action is better if taken after eating. In studying my records and memoranda of cases, I find that the treatment by salicin has often been unsatisfactory. The proportion of unsuccessful cases was about twenty-five per cent.; but in some cases the effects of this remedy given alone have been remarkable. I have full records of one case of severe dyspepsia of ten years' standing that was completely relieved in a week without any return, now for more than a year. The bismuth subgallate, however, is almost a specific in cases of purely functional dyspepsia with flatulence. While I have full records of a few obstinate cases, the histories of most are merely short memoranda, and of many I have no records. Since December 8, 1892, when I began to use the bismuth subgallate, I have noted only two cases in which it gave no relief, there being no evidence of organic disease. Both of these were in hysterical women. In both I used salicin and salol; and in one, salol, salicin, naphthalin, and aristol. These were cases of long standing which had resisted treatment of every kind, and they soon passed from under my observation.

I was led to use bismuth subgallate by seeing it recommended as a valuable remedy in the diarrhoea of children,

acting as a disinfectant. I first employed it in a case of dyspepsia of eleven years' standing which is so remarkable in some of its characters that I shall give farther on an account of it somewhat in detail. Its action in this case was so favorable that I began to prescribe it very largely, almost invariably with remarkably satisfactory results, and I continue to use it almost daily. I have no records of many of my cases, but have been careful to note the few instances in which I have been disappointed in its effects, with certain cases in which its favorable action has been truly remarkable. I have already mentioned the two cases in which it seemed to be of no benefit. The following are a few of the cases of remarkably prompt and favorable action: A case of alcoholism of twenty years' standing, with habitual dyspepsia for the last five or six years; bismuth subgallate gave almost instant relief; the flatulence and distress disappeared in twenty four hours, and did not return, except in a very mild degree, when they were usually relieved by a single dose. While under other treatment for alcoholism, this condition was relieved. The patient has taken no alcohol for several weeks and has no craving for it. A case of dyspepsia of four years' standing, with a chronic diarrhoea, was entirely relieved in five days by the use of the bismuth subgallate alone. A case of dyspepsia of more than thirty years' standing was promptly relieved by bismuth subgallate alone. In this case, every few weeks the trouble returns and is relieved by two or three doses. I am indeed no longer surprised at results from the use of this remedy which first seemed to me remarkable; and now I confidently expect prompt and favorable action. I have been in the habit of prescribing it in capsules containing five grains each, but lately have had it prepared in the form of tablets. In this latter form it is more convenient and seems to act more favorably.

The following case, which I give on account of certain remarkable and interesting features, is the first in which I used bismuth subgallate.

On November 16, 1892, a gentleman, about forty years of age, tall and robust, with the appearance of perfect health, consulted me in regard to a long-standing dyspepsia. He had suffered from indigestion with considerable pain for a long time, and about eleven years ago, under the advice of a physician, had adopted an exclusively milk diet. Since that time he has taken milk and nothing else, consuming about five quarts in the twenty-four hours. He has been in the habit of taking milk about every half hour during the day and at variable intervals at night. If he goes more than an hour during the day without milk he has gastric and intestinal pain which soon becomes almost unbearable, but is soon relieved by about half a pint. With the pain he has great flatulence and violent eructations. During the past eleven years he has engaged in literary work and has traveled extensively in this country and abroad. While taking milk, however, he has felt well, slept well, taken considerable exercise, and his bowels have been regular. His personal and family history is good in every respect, and a careful physical examination failed to reveal structural disease of any organ. He wished to be treated for what he called the "milk habit."

I directed him to cut off milk promptly and absolutely, and to take three meals a day without restriction as to quantity or kind of food, except that he was to avoid sweets and pastry and

be moderate in the use of wine at dinner. I prescribed ten grains of salicin four or five times daily, and always to take a dose after eating. On the evening of the first day of treatment he went to a dinner party, eating and drinking of everything. He described his sensations at the dinner as most delightful, enjoying his unaccustomed food immensely; but his teeth were sore and his jaws tired after eating, as he had not masticated for eleven years.

On the following day he reported that he had suffered intensely with abdominal pain and eructations, but nevertheless had taken breakfast, lunch, and dinner, and had abstained from milk. I continued the treatment and directed him in addition to take sodium bicarbonate five or six times daily to relieve the flatulence.

On the third day he reported that he was doing fairly well, but still suffered considerably an hour or two after eating.

On the fourth day he was about the same. I discontinued the salicin and prescribed naphthalin, five grains every four hours. During the entire treatment he took sodium bicarbonate freely and as often as he felt much discomfort from flatulence.

On the fifth day, having eaten like other persons from the beginning of treatment, taking no milk, he had slightly improved. He thought the naphthalin gave him considerable relief.

On the sixth day he was doing very well, and the treatment was continued. He had become so much encouraged that on the fifth and sixth days he took supper late at night, with some excess in eating and drinking.

On the seventh day he was not so well. The indiscretions in diet of the fifth and sixth days, as he thought, gave rise to considerable pain with flatulence and vomiting. At night on the sixth day he took about half a pint of milk, which gave great relief. I discontinued naphthalin, substituting five grains of salol every two to four hours, and allowed a glass of milk at night.

On the tenth day he reported that he had done fairly well. The treatment was continued with the addition of a glass of milk on rising in the morning.

On the twelfth day he had improved, the salol acting well. The treatment was continued.

On the fourteenth day he reported as not so well, having had a great deal of flatulence. I continued salol and prescribed ten grains of salicin before eating.

On the sixteenth day he was about the same. I prescribed a teaspoonful of listerine after eating.

On the twentieth day he reported no progress. The listerine seemed to have no effect. I discontinued listerine and prescribed ten grains of menthol as required.

On the twenty-third day he reported that the menthol seemed to act unfavorably. I then discontinued other remedies and prescribed ten grains of bismuth subgallate three times daily after eating. On the following day he went to Washington for six days.

On his return from Washington—the thirtieth day—he reported that his diet had been unrestricted and that he had been perfectly well since first taking bismuth subgallate. From time to time he took, in addition to the bismuth subgallate, sodium bicarbonate to relieve slight flatulence with eructations. He then left the city for an extended journey abroad.

In May, 1893, six months after, I received a friendly letter from the patient, in which he made no mention of any digestive disturbance.

In August, 1893, the patient called upon me and reported that he had traveled extensively, at times subjected to very unfavorable conditions of diet; that he had been perfectly well

and strong; had lost some flesh, which he regarded with satisfaction; had taken very little sodium bicarbonate, and occasionally, though rarely, a few doses of bismuth subgallate. His diet was unrestricted, and he considered himself permanently cured.

I have given rather an extended account of this case to illustrate the unsatisfactory results following the administration of a great variety of antifermentative remedies until the bismuth subgallate was prescribed. This remedy promptly produced marked improvement, and, in the light of my subsequent experience, it seems to me that if it had been used earlier the recovery would have been much more speedy.

It was not my intention to discuss the question of diet in the causation and treatment of fermentative dyspepsia. Of course, a cure is established only when a diet practically unrestricted may be used with impunity. During the treatment of these cases patients are simply directed to avoid excesses in food and drink and to eat little or no pastry or sweets.

THE WITHHOLDING OF REPORTS OF OPERATIONS FOR THE RELIEF OF CANCER OF THE THROAT.*

BY D. BRYSON DELAVAN, M.D.

It is but too well known by all that the results of the present methods for the treatment of malignant disease of the throat are in the main far from satisfactory. The sole aim of this paper, therefore, will be to urge upon those in whose power it lies the importance of increasing our practical knowledge of the subject by their contributions, and thus enabling us to judge fairly and accurately as to our actual ability to deal with this variety of disease.

In presenting it, the writer at the outset earnestly disclaims either the intention or the desire to reopen the discussion as to the relative merits of any one method of operation compared with another. Still less does he wish to throw discredit upon any method of operation which may have been employed, or to criticise any operator who may at any time, or in any place, have labored in this field of surgery. It has been his misfortune to see a considerable number of cases of cancer of the throat, and to learn from them, and from the recorded experience of others, the painfully well known fact that malignant disease of this locality, no matter of what histological character it may be, is always a most serious affection at the best, and that, occurring in the form of epithelioma, is practically an absolutely fatal one. More than once new methods have been suggested which have seemed to offer a fair prospect of increased success; some of these, in the case of the less malignant forms of growth, have proved to be of decided value. In epithelioma, however, they have generally proved unsuccessful, and the record of such as have been reported is little better than a long and disheartening series of failures. Such indeed it must appear to the patient

himself when seeking information upon this subject. The difficulties in the way of an intelligent prognosis have, up to the present time, seemed almost insurmountable. Of course, it is impossible to judge of the actual result of any series of operations until after the lapse of a considerable amount of time. With cancerous disease this is particularly the case, inasmuch as the very criterion of success of an operation is the extent to which the patient's life has been prolonged by it, and most of the operations which we have under consideration have been proposed too recently to enable us to obtain satisfactory statistics as to the actual prolongation of life which they have accomplished.

To illustrate the difficulty of obtaining accurate statistics, let us take the history of thirty operations upon the larynx in cases of epithelioma, already publicly reported or gained by the writer from private sources. They represent the work of several of the most eminent of living surgeons. Such cases should be divided into three classes: First, those in which the history is complete up to the time of the patient's death. Second, those in which, at the time of the writing of the history, the patient is still living, but suffering from recurrence of the disease. Third, those in which at the date of the history the patient is alive and well.

It is plainly unfair to confine our deductions to the reports of the first class without taking any consideration of classes two and three, as witness the following results:

In the thirty patients operated upon and dead, the aggregate of the length of life was two hundred months, or sixteen years and two thirds; but it is often stated that the average duration of life in cases not operated upon is about eighteen months from the time at which operation would be likely to give promise of some success. In my own experience, by the way, this estimate is too liberal. Assuming it, however, to be approximately correct, the aggregate length of life of thirty patients unoperated upon would be about five hundred and forty months, or forty-five years. Thus it would appear that in these unsuccessful operations there had been lost to the thirty patients no less than twenty-eight years. In so far as the record concerns class 1, this is true. When we come to compare it with collections of cases representing classes 2 and 3, however, it at once shows a wide variance. And yet, until the histories in these classes shall have been completed by the death of each patient, it will be impossible to arrive at any accurate conclusion.

Again, one of the best summaries extant is that of Kraus.* In this he studies together the cases of laryngectomy collected by various authorities after the death of Emperor Frederick. In all they number four hundred and sixty-six, fifty-nine, or nearly thirteen per cent., of which he claims as successful because in them the patients were still alive, and had not suffered recurrence for at least one year after the date of operation. But it is hardly fair to say that a case is cured simply because the patient has managed to survive one year. The lapse of a few years more would show a marked falling off, as is proved by Kraus's own statistics,

* Read before the American Laryngological Association at its fifteenth annual congress.

* *Allgem. Wiener med. Zeitschr.*, 1891, No. 15.

for, of twenty patients who lived for over one year, fifteen died before the end of the third year. Moreover, recurrence may take place after the lapse of a considerable amount of time. Even the fact that death may have occurred without recurrence is not necessarily a proof of the success of the operation, since the very demise of the patient may have been more or less directly due to his having been subjected to so severe a surgical procedure.

Discouraging as these inaccuracies may appear, it has seemed to the writer that the time was rapidly approaching when the number of cases operated upon by means of the various recognized methods would have increased to such a degree that a clearer idea could be gained of their relative value as compared with each other, and that a sufficient length of time would have elapsed to prove their ultimate results, so that the question as to whether they actually succeed in prolonging life might be definitely settled, and if they do, the approximate extent to which they may be depended upon to so prolong it. While many cases and collections of cases have already been recorded, and statistics have thence been deduced and offered to us, there is nothing which can to-day be relied upon as satisfactory in any department of this subject, either in the case of operations performed by the natural passages or of those of the more radical and heroic kind. This is not alone owing to the small number of cases operated upon. It is certainly due in part to the failure of many operators to record faithfully and fully all of their cases. Of course, it is not to be supposed that such operations are common. Doubtless they are not, and, when performed, they have not seldom proved so unfortunate that to have reported them would have been an unwelcome task. Many operators, it is true, have been most careful to publish everything connected with their work—as, for example, the excellent reports of Billroth, Hahn, Butlin, Lanz, David Newman, Cheever, Solis-Cohen, Fowler, Gerster, and others. But in this, as in other departments of medicine, it too often happens that the unsuccessful cases are allowed to pass unnoticed. Where this is the case and the successful ones alone are put on record, it is plain that the latter will be misleading and, to the statistician, worse than useless. To secure satisfactory knowledge, all cases, good and bad alike, must be reported.

It is certain that, both in this country and abroad, published records have not been made of a considerable number of important cases, but that many have been allowed to pass unnoticed, and thus the lessons that might have been learned from them lost. If the truth must be confessed, this is probably quite as true of the simpler operations from within as of the capital ones, so that in considering the question we do so entirely without prejudice. The substance of the whole matter is this: namely, that heretofore the discussion of the value of the various methods has been based partly upon theory and partly upon evidence too meager to afford substantial proof. What is needed to-day is the largest possible collection of reliable data, embracing all of the different operations which are performed for each of the separate manifestations of cancer of the throat. The gravity of the situation is such, and the need for help so urgent, that we hardly go too far when we in-

sist that a full, painstaking, and accurate account be given of the history of every malignant growth removed from the upper air passages. With such material at our command, many at least of our present difficulties and doubts might be removed, and while it would not at once be possible to solve them all, it would, without question, enable us to advise with more intelligence and to act with materially increased prospects of success.

Thus it might be definitely determined whether or not a certain operation was under any circumstances justifiable, and if justifiable at all, under what circumstances it would be likely to yield the best results. Again, much more might be learned as to the relative value of different methods—as, for example, the operation for complete laryngectomy as compared with partial, or of laryngectomy in general as compared with intralaryngeal operation, or as to whether the average duration of life was greater where a cancerous tonsil was removed by external incision, division of the jaw, and extensive dissection, than in cases operated upon by external incisions of a simpler nature.

Indeed, as we survey the field many questions arise which are in need of definite settlement and which can only be determined by the study of full and accurate statistics. Thus, a fair comparison should be made between the results of operations for the removal of tumors of the pharynx and nasal cavities by severe preliminary operations, such as Annandale's, and those in which the galvano caustic loop has been employed; between laryngectomy and intralaryngeal operation, etc. Again, one method may be found to prolong life to a greater degree than another, and yet not indefinitely extend it. Laryngectomy usually results in death within three years, even although recurrence may not have taken place. May this not be due in many cases to the general effect of the operation? Certainly in extensive operations about the nasal cavities profound shock may result from the necessary interference with the various important nervous structures in the neighborhood. Yet again, in view of the fact that the earlier statistics of laryngectomy are better than those of recent years, may it not be possible that this operation, if practiced at all, should be performed by a few highly skilled and successful surgeons, rather than committed to those whose experience in it has been limited? These are but a small part of all the unanswered questions. Let every case then be reported with careful detail, not only as to the method of operation, but, almost more important still, with clear and full description of the after-care of the wound and of the special difficulties and accidents presented with each individual, for the after-care is often by far the most trying and hazardous part of the whole matter.

And, finally, when we have done our best and have exhausted our resources, in case all of our present methods of curing carcinoma should be proved practical failures, even this unhappy result would be of benefit in destroying delusive hopes, and, what is of far greater practical importance, in stimulating us toward the accomplishment of that not impossible discovery from which it shall be learned that cancer may be cured by other means than the knife.

ARTHRITIS DEFORMANS OF THE LARYNX.*

By W. E. CASSELBERRY, M. D.,

CHICAGO,

PROFESSOR OF THERAPEUTICS AND OF LARYNGOLOGY AND RHINOLOGY
IN NORTHWESTERN UNIVERSITY MEDICAL SCHOOL (CHICAGO MEDICAL COLLEGE);
LARYNGOLOGIST TO WESLEY HOSPITAL, ETC.

The propriety of the introduction of this title into laryngeal nomenclature must depend upon the final disposition by pathologists of the same question relative to arthritis deformans in general, the disease which is also termed rheumatoid arthritis. If it be conceded, as is now claimed by most writers on the subject, that arthritis deformans is quite independent of rheumatism on the one hand and of gout on the other, then its laryngeal complication, which I believe I am about to describe for the first time, will be entitled to independent consideration. If, however, the disease be eventually relegated to the class of rheumatic affections, then it is hoped only that this contribution may prove of interest as descriptive of a rare laryngeal phase of the latter disease.

Concerning the individuality of arthritis deformans, Dr. Leonard Weber, in the *Reference Handbook of the Medical Sciences*, says: "It is distinguished from gout and rheumatism by the peculiar morbid changes it produces in the articular tissues and by the absence of any known abnormal state of the blood." "The name 'rheumatic gout,' which has been given to it, is evidently a misnomer, as it is neither gout nor rheumatism."

From careful studies of the morbid anatomy of arthritis deformans, R. Volkmann, cited by Weber,† recognizes the rapid proliferation of the articular cartilaginous elements, particularly on the free surface of the cartilage, as the essential factor of the disease, together with subsequent absorption of the cartilages. Garrod‡ failed to discover any pathognomonic changes in the blood, and Weber* states that it is a fact that uric acid has not been found in the blood, and that analysis of the urine has failed to show unusual increase of uric acid or urates. Moreover, deposits of urate of sodium, which are constant in gout, are not found in arthritis deformans, and the changes which are found are quite different also from those of simple articular rheumatism. Inasmuch as Charcot and others have demonstrated an ætiological relationship to exist between certain spinal diseases and other peculiar morbid states of the joints, a trophoneurotic origin of arthritis deformans has been suggested.

Substantially the same views relative to the independence of this disease are expressed by Senator in von Ziemssen's *Cyclopædia*, and by Howard in Pepper's *System of Medicine*.

In February, 1893, I was requested by Dr. E. J. Doering, of Chicago, to see in consultation Mrs. S., a widow, about fifty-eight years of age, in affluent circumstances, but of plain habits and mode of life. She had been suffering for some weeks from laryngeal dyspnoea, which was now so severe as to occasion marked inspiratory stridor and a noticeable expiratory noise.

The laryngeal image, at the first trial, was only fairly satisfactory, but gave one the impression of acute laryngitis of moderate intensity only and without adequate explanation of the dyspnoea, for there was no oedema and the ventricular bands were so little swollen that on the phonation of the vowel "e" the vocal cords could be seen approximated in the median line. On cessation of this sound the epiglottis would fall so quickly that the cords could not be viewed during the stage of abduction. The arytenoid eminences appeared swollen and their movements restricted, but they were not grossly distorted. After a few days' training a much better view of the larynx was obtainable, and I then observed that abduction of the vocal cords could not take place, their separation at best, whether during ordinary quietude or on forced inspiration, being so slight that but the smallest possible space between them was provided for respiration. Another conspicuous feature of the view was a peculiar thickening or swelling of the posterior ends of the vocal bands, sufficiently marked to cause each posterior end to bulge perceptibly downward as well as upward, and to project into the rima glottidis beyond the line of the purely fibrous part of the cord, encroaching upon its fellow of the opposite side. The part of the vocal cord thus affected is commonly designated the cartilaginous portion, because of the projection into it, as it were, of the vocal process of the arytenoid cartilage, which gives attachment to the fibers of the cord proper, or the presence in its substance of this vocal process in the form of a sesamoid cartilage, detached from the body of the arytenoid, as described by Solis-Cohen, and because, further, of the cartilaginous film imbedded therein in female subjects, as described by Seiler. The position of the vocal process formed a distinct "line of demarcation" between this curiously thickened posterior end of the vocal cord and its main portion or purely fibrous part, the latter being congested and relaxed, but not enlarged or thickened. The appearance was suggestive of inflammatory infiltration in the deep substance of this part of the cord, and, in connection with other features of the case, it is a reasonable inference that the curious enlargement at this point was due to proliferative changes in the cartilaginous elements, especially as the arytenoid cartilage itself was likewise involved. I have mentioned that the arytenoid eminences appeared more than usually prominent, but not unequally so, and that their motion was restricted in correspondence with the want of the power of abduction of the vocal bands. It seemed reasonably certain that this inability of the vocal cords to separate was due to ankylosis of the crico-arytenoid articulations. A similar aspect could be produced only by paralysis of the posterior crico-arytenoid muscles in conjunction with acute laryngitis, but "posticous paralysis" would not be accompanied by the peculiar condition of the posterior ends of the vocal cords above described, or by enlargement of the arytenoid eminences. The stridor of "posticous paralysis," furthermore, is inspiratory only, the cords on expiration presenting upward like a dome with an elliptical space between them. Moreover, neither the history nor the subsequent course of the case would justify a diagnosis of abductor paralysis. Daily opportunities were afforded for laryngoscopic observation, and during the following two weeks the condition remained practically unchanged. The dyspnoea gradually exhausted her strength and a time was appointed for the operation of tracheotomy, but just then respiration became somewhat easier and it continued to improve until, at the end of six weeks, she breathed noiselessly and, during quietude, without conscious effort. The aspect of the larynx, however, had changed but slightly. The congestion was less marked, the vocal cords appeared paler and thinner, and the space between them on inspiratory efforts at abduction was somewhat wider, with a corresponding slight increase of motion of the aryte-

‡ Cited by Weber. Loc. cit.

* Loc. cit.

noids, but the cords could not be estimated to separate, even now, more than one sixth part of the natural distance, and the arytenoid eminences and the posterior ends of the vocal cords presented the same appearances. Her larynx was again free of viscid mucus, which had intensified the dyspnea, and the cough had subsided so that the patient expressed herself as feeling about as well as usual. True labored respiration was at once excited by any considerable exertion, but to more or less of this she had been accustomed for years.

Evidently this attack had not been one alone of ordinary laryngitis, but rather of an acute exacerbation of a chronic laryngeal arthritis, an inference which is further justified both by the history and the presence of a general arthritis deformans. The patient previously had twice suffered, at intervals of two or three years, from similar attacks, the second seizure having been equally severe, but of shorter duration. She chanced at that time to be traveling in Germany, and was under the treatment of a competent laryngologist, who subsequently told her that the opening of the larynx was unusually small, and that the laryngeal disease was connected with her so-called rheumatic gout. This general arthritis has affected the patient progressively for from ten to fifteen years or more, having commenced so insidiously as to have attracted but little serious attention during its earlier years. It closely corresponds to the typical form of polyarticular arthritis deformans, as described by Weber* and others.

The joints of the right and left sides are affected symmetrically throughout, a feature which is manifested likewise in the two crico-arytenoid articulations of the larynx. The hands are characteristically distorted, and distorted wonderfully alike, displaying prominently the enlarged and nodular condition of the ends of the phalanges and the heads of the metacarpal bones. The fingers are no longer articulated in a straight line with the metacarpal bones, but are all partially dislocated outward in the direction of the little finger. The joints are stiff, but not immovable, and she has succeeded in counteracting the usual tendency to flexion of the fingers by regularly maintaining them extended against the bedding at night. The thumbs are dislocated backward. Her wrists exhibit similar nodosities and are stiffened. The elbows and shoulders are less affected, the disease having manifested itself first and most severely in the extremities, and especially in the hands. Her feet and ankles are similarly affected, but not conspicuously so. The left knee is involved to such an extent that in sitting she must maintain it in a position of extension. The hip joints as yet seem but little affected.

The patient has never had a typical paroxysm of gout or suffered from acute articular rheumatism; in fact, she states that her disease has not at any time been accompanied by pain, but merely at certain periods by a sense of discomfort which approaches pain only on forced movement of the affected joints. Nor has she experienced any pain in the region of the larynx, a point which seems further to distinguish this laryngeal complication from rheumatism, which, when affecting the larynx or pharynx, has quite invariably been described as accompanied by pain, often severe and lancinating in character. All treatment in the past and during the recent seizure formulated on the supposition that her disease might be either gout or rheumatism has uniformly and utterly failed.

Treatment directed especially to the chronic arthritis deformans of the larynx has been attempted only at times of acute exacerbation of the disease, and during the last attack it was directed chiefly toward relief of the dyspnea. She could inhale fine sprays into the larynx fairly well if the tongue were

held out and the head thrown backward. A preliminary spray of a two-per-cent. solution of cocaine would afford prompt, albeit temporary, mitigation of the dyspnea, doubtless by contracting the congested vessels of the mucosa, and would also, by benumbing the parts slightly, permit of a more thorough application of subsequent sprays. An alkaline and antiseptic spray, containing sodium bicarbonate, sodium borate, menthol, oil of eucalyptus, oil of gaultheria, glycerin, and water, served to augment and prolong the good effects of the cocaine and to cleanse the larynx of viscid mucus. Later, sulphocarbolate of zinc, ten grains to the ounce of water, was employed with benefit. As a final inhalant I would use the following soothing petroleum combination, which in this case, as in many others of acute inflammation of the larynx, trachea, and bronchi, I have used with much comfort and benefit to the patient:

R Ol. pini canadensis..... ℥v;
Ol. gaultheriæ..... ℥ij;
Ol. eucalypti..... ℥ij;
Menthol..... gr. j;
"Benzoinol"..... 3 ij;
"Vaseline oil"..... q. s. ad 3 j.

M. Sig.: To be used with a double-bulb atomizer.

The persistent use of these remedies simply served to keep the larynx free of mucus and the congestion at a minimum, but without them I am convinced that the operation of tracheotomy could not have been avoided.

After their use, especially at night, when the dyspnea seemed most urgent, the exhausted patient would obtain sufficient relief to permit of much-needed rest and slumber.

LARYNGITIS HIEMALIS.*

By J. C. MULHALL, M.D.,

ST. LOUIS.

DURING the last twelve years I have written notes in my case-books of nine cases of an affection of the larynx in which there existed such a uniformity of signs and symptoms peculiar alone to this disease, and as yet, to my knowledge, unwritten about, that I have thought it worthy of the special title under which I beg leave to present it for your consideration.

It is simply a variety of subacute catarrhal laryngitis, in which the secretions are, *ab initio*, adhesive crusts, mechanically producing dysphonia, more often complete aphonia, and occurring *alone during winter*. I have adopted the term "winter" laryngitis for the following reasons: I have never seen the disease except in winter. In several of these selfsame patients, who have had attacks of laryngitis in summer, the crust formation has not occurred, aphonia was absent—in a word, it pursued the ordinary course of a non-febrile, subacute laryngitis. Two of my patients, completely aphonic, having been sent to the warm, moist air of Florida, lost all traces of the affection—one within forty-eight hours, and one within a week after arrival in that State. One of them being compelled to return to St. Louis before our cold weather had ceased, was, on the second day of her return, seized with her former laryngeal symptoms. I have had several such experiences as the following: The patient enters the consulting room com-

* Read before the American Laryngological Association at its fifteenth annual congress.

* *Loc. cit.*

pletely aphonic. With a warm salt-water laryngeal spray, all crusts having been detached and coughed out, the voice has at once returned more or less pure. On the following day the patient has returned with the intelligence that within two hours after leaving the office the voice had again become lost. On the appearance of several successive days of warm weather in the winter these cases have rapidly improved. It therefore seems to me that continued cold weather is the important factor—the exciting cause.

The predisposing factor—that which causes the larynx to yield this perverted secretion—is as much a mystery to me as the foul perspiration of certain individuals otherwise healthy. I have found it associated with no particular diathesis, age, occupation, unhygienic surrounding or *personnel*, or faulty condition of other bodily organ, including the nose.

The crusts adhere more closely to the true than the false cords, cling with great tenacity to the inter-arytenoid fold, and are often found on the under surface of the true cords. In St. Louis they are often black, being thus discolored by the soot-laden atmosphere. The evidences of inflammation in the larynx are usually quite slight, and I have often been surprised, after having cleansed the larynx, to see the true cords white and without suspicion of erosion or thickening. In one patient, however—a saloon keeper, a slave to alcoholic and other excesses, utterly careless as to the quality of his voice, and who would only apply for treatment when he had been quite aphonic for a week or two—a general laryngeal thickening has taken place and he is dysphonic even in summer, though no crusts are ever present in this season. Each winter, however, with the first appearance of cold weather, the crust formation occurs. The aphonia and dysphonia are mechanical, the crusts preventing cord vibration and approximation, and these symptoms alone cause the sufferer to seek relief. The tickling cough is but slight, and the patient soon learns the futility of attempting to clear the throat by forced coughing, rasping, and hawking, and soon ceases these efforts.

The disease may be acute and last but two or three weeks, but may readily, without appropriate treatment, last the entire winter. It may occur but once in the lifetime of a patient, or may be a relapsing disease. It may occur with the first fall of the thermometer to 30° F., even without the precipitating factor, "catching cold." In two such cases I have not been able to satisfy myself with the laryngoscope that any inflammation whatever existed.

One not familiar with this clinical picture—for it is rare—might suggest that this is but a variety of the well-known "laryngitis sicca." This latter is, however, nearly always associated with pharyngitis sicca or rhinitis atrophica, being *sequential* to these conditions. It is essentially a chronic disease, the secretions often fetid, and is merely modified by climatic conditions. In the cases I have described there is associated no other bodily ailment.

The milder often readily yield completely to treatment. I have found hygiene, both in the cure and prophylaxis, of most importance, such as the wearing of light woolen undergarments, thick-soled shoes, without rubbers; the

avoidance of overheated apartments, especially furnace-heated houses; the sleeping in a cold room, cold-water sponging, silence in the open air, avoidance of stimulants, careful dieting, etc.

Locally, after having first cleansed the larynx, I have found a cold spray of vaseline and eucalyptol, ten minims to the ounce, two drachms to be used at a sitting, of most service. The cold, wet throat pack at night and the internal use of muriate of pilocarpine, combined with muriate of ammonia, complete what I have found to be of service.

RHINITIS ŒDEMATOSA.*

By J. C. MULHALL, M. D.,

ST. LOUIS.

SOME years ago a patient entered my consulting room desiring relief from obstructed nasal breathing. I saw nothing abnormal anteriorly, but posteriorly saw what I hastily concluded was a large, soft polypus projecting from the right nostril. I acquainted the patient with my diagnosis, and requested his return on the following day for operation. He complied, when, to my discomfiture, I saw nothing in either nostril to remove. I acknowledged my error, and began to ask questions—a proceeding I had disdained on the previous day. I then learned that the obstruction was intermittent, sometimes bilateral, again unilateral, sometimes completely absent. The discharge was scanty and purely serous. This was my first knowledge of such a nasal disorder.

I have seen since then six cases. It consists of an infiltration of pure serum into the connective tissue overlying the inferior and middle turbinate bones. It may be general or limited. For example, in a case seen by Dr. Glasgow and myself, the œdema was limited to the posterior half of the left middle turbinate, projected into the pharynx, resembled very much a cyst, and caused intense pain, lachrymation, and a flow of acrid, thin serum. The œdema is sometimes migratory. It may affect exclusively the anterior end of a middle turbinate to-day, disappear in a day or two, and reappear at the posterior end of the inferior turbinate. The discharge is usually slight and consists of limpid serum. It may be acute or chronic, the latter causing little suffering beyond that incident to obstructed nasal breathing. In appearance, when confined to a small area, it strikingly resembles a recent myxoma, especially when situated about the hiatus semilunaris or olfactory fissure; and even since my original experience I have been for a moment deceived. The probe, however, soon dissipates doubt. Unlike other vaso motor troubles in the nose, it is unaffected by cocaine: When punctured with a bistoury it very slowly yields serum. The incision heals very rapidly, and the parts can not be drained in this way. It may occur, as it did in two of my cases, in connection with bronchial asthma. Its exact relationship I have not been able to determine. I have one patient in whom I have seen it coincide with the asthma. Yet I have seen the same patient

* Read before the American Laryngological Association at its fifteenth annual congress.

suffering asthma without nasal oedema, and also suffering nasal oedema without asthma. In this patient, therefore, one may feel sure that there is a causative element common to both, selecting both vaso-motor areas—the nose and bronchi—at one time, or but one, according to the intensity of the exciting cause. In the other four cases asthma was never present. In one case the nasal oedema was chronic and unilateral; bronchial spasm of mild degree nearly always present, varied by occasional nocturnal paroxysms of great severity. The disease is certainly a neurosis, and yet stands quite apart from that class of cases where the precipitating factor is from without—such as rose cold, hay fever, ipecac or animal asthma, and the like diseases, where the reflex cycle commences in the nose. Again, it has nothing in common with that form of vaso-motor coryza characterized by sneezing, the profuse discharge of serum, often a pallid mucous membrane, occurring independently of season, occupation, or surrounding; often lasting years and readily controlled, though not cured, by a system of treatment addressed to the sympathetic system of nerves. In rhinitis oedematosa this treatment has been of no avail. It seems to me almost certain that the exciting cause is from within, and most probably intestinal ptomaines form the chemical irritant to the sympathetic nervous system.

In two cases of acute migratory oedema the affection was coincident with a mild degree of icterus, and when the jaundice had disappeared and all treatment was directed to this end, no local treatment whatsoever having been instituted, the nasal oedema disappeared. These two cases had never before had nasal disease of any kind. In three cases of relapsing oedematous rhinitis complicated with bronchial asthma there existed the group of symptoms familiarly known as biliousness. When, by treatment directed to the correction of this condition, the urine and feces had resumed their normal color and quantity, the tongue had become clean, intestinal fermentation had ceased, the appetite had returned—in a word, the alimentary canal had resumed its normal function—the asthma and nasal oedema disappeared. Relapses were always accompanied by the digestive disorder.

From analogy, since we call the one peptic asthma, we might also speak of peptic oedema. I therefore believe this disease to be always of systemic, mostly of biliary origin.

Does a predisposing factor exist by virtue of abnormal contact points in the nose? In the acute cases neither hypertrophy, deviated bone, nor cartilage were found. In two chronic relapsing cases deviations of the septum were rectified, without, however, preventing relapses. In one the patient was entirely free from asthma and nasal oedema for six months—a longer period of immunity than he had enjoyed in ten years—but relapse finally occurred.

Anatomically considered, one might expect nasal oedema in Bright's disease, but, though I have examined not less than fifty cases of chronic nephritis to this end, I have yet to see such a case. I was therefore not surprised to find in these cases no evidence of kidney trouble. It occurred at no special season of the year, exhibited no peculiarities with regard to social conditions, sex, or age,

except that I saw no case in children. The atmospheric factor plays a part. In the case of the lady, wife of an army officer, seen with Dr. Glasgow, her two attacks, three years apart, coincided with removal to St. Louis on both occasions. She quickly recovered after leaving St. Louis. In two cases permanent relief from asthma and nasal oedema followed permanent residence in southern California. Some atmospheric factor, plus deranged digestion, plus central instability, plus a hyperæsthetic nose, probably unite in the ætiology of a single case. In the treatment the one great thing not to do is to spray the nose. Even a weak spray of cocaine, or vaseline variously medicated, aggravates instead of helping. All local treatment, except perhaps scarification, should be avoided. This is especially true of the acute cases. In chronic cases I should regard it good practice to correct nasal abnormality. All efforts should be addressed to correcting the depraved condition of the alimentary canal. Intelligent dietetics, hydrotherapy, well-ordained physical exercise, massage, nerve rest, and the avoidance of drugs, form the basis of treatment.

THE EARLY TREATMENT OF CARCINOMA UTERI.

By HOWARD A. KELLY, M.D.,

PROFESSOR OF GYNÆCOLOGY AND OBSTETRICS IN THE
JOHNS HOPKINS UNIVERSITY;
GYNÆCOLOGIST AND OBSTETRICIAN TO THE JOHNS HOPKINS HOSPITAL.

THE large number of hopeless cancer cases constantly applying to me for relief have induced me for the past three years to adopt certain stringent rules with regard to my own patients, which I have taught for the same period in my lectures at the Johns Hopkins Hospital.

The end in view is twofold—first, by treating cervicæ liable to become cancerous, and thus prevent the formation of this neoplasm, and, secondly, to detect cancer of the cervix at a sufficiently early date to successfully eradicate the disease.

1. It is the duty of the obstetrician to see each patient at his office from two to three months after her confinement, and there to examine and make a careful record of the condition of the pelvic structures, stating accurately what lesions have been produced by the confinement.

2. Cervical lacerations should be carefully described, noting the position and depth of the tear and the appearance of the lips. Lacerations require no treatment when the lips are thin, uninfiltated, and lie together. Thick, infiltrated, and everted lips associated with cervical catarrh call for depletory treatment followed by repair of the laceration.

3. Every woman who has passed thirty-five years of age and has borne a child should have this examination made without delay by a competent physician, and if the cervical lips do not appear perfectly sound she should be kept under observation and examined at intervals of from six to eight months.

4. Every woman over thirty-five, with a cervical tear, should be examined at least once a year for ten years, or longer, if the appearance of the lacerated area is not perfectly healthy.

5. These rules apply with special force to patients whose family history shows a marked inclination to cancerous diseases.

If these rules are conscientiously observed there is not a shadow of doubt but that thousands of lives would be saved yearly in this country alone by timely interference with a disease so markedly local and accessible in its origin.

I feel that while we are searching for a cure for cancer, the line of progress in the immediate future for the gynecologist is clearly in the direction of prophylaxis and anticipation, either preventing or discovering the malady in its earliest stages.

A PRELIMINARY NOTE UPON THE RELATION OF THE BACTERIUM COMMUNE COLI TO APPENDICITIS.

By GEORGE RYERSON FOWLER, M.D.,
BROOKLYN.

In an article by Dr. Morris, in the October number of the *Annals of Surgery*, the following paragraph occurs (page 369):

"The phenomena of infectious appendicitis vary according to the predominating species of bacteria in any given case, but the *pyogenic streptococci* and *staphylococci* do most of the wide infecting" (Italics my own).

The active rôle of micro-organisms in producing the phenomena of appendicitis was pointed out by Talamon, according to a statement made, by that writer in a recent publication upon the subject,* more than ten years ago. Four years ago (1889) Laruele, quoted by Talamon (page 53), declared that the *Bacterium commune coli* was the veritable agent of peritonitis by perforation. Welch,† of the Johns Hopkins University, noted the presence of this microbe in six cases of peritonitis due to perforation, and in two instances it was due to an intestinal affection in which no perforation was present.

In a paper read before the American Surgical Association, May, 1893, by Dr. Roswell Park, of Buffalo,‡ entitled The Importance to the Surgeon of Familiarity with the *Bacillus Coli Communis*, among other suppurative intra-abdominal conditions in which this bacillus was found, three instances are reported in which its presence was demonstrated in connection with appendicitis.

Of recent years the innocent character of the *Bacterium commune coli* has been doubted by many. Within the past few months there has been a disposition to attribute to this agent not a few suppurative inflammatory conditions exclusive of those occurring in organs invested with peritonæum or adjacent to the intestinal tract.* It is more than likely that a micro-organism which may take upon itself migratory powers and pathogenetic characteristics, produc-

ing inflammatory lesions at points remote from its natural habitat, would produce distinctive effects upon tissues with which it might be brought in contact from direct continuity of surface, particularly if these tissues, in the process of evolutionary changes, are deprived to a great extent of the quality of vital resistance—the only protection which living structures possess, of themselves, against the invasion and destructive effects of bacteria in general.

In view of these considerations, and the further fact that so recent an observer as Dr. Morris, in a carefully prepared article upon the subject, has failed to mention the causative relation which in all probability exists between the *Bacterium commune coli* and appendicitis, I desire to place upon record the following observations: The cases were operated upon by myself, and included eight instances of the disease taken at random in my hospital service whenever the opportunity offered for making cultures. The method of inoculation consisted of either the employment of a heat-sterilized platinum needle, or of gathering the fluid upon a piece of sterilized gauze and transferring this to a sterilized culture tube. The appendix itself was placed immediately after removal in a heat-sterilized bottle and conveyed to the Hoagland Laboratory, where one of my assistants, Dr. A. F. Bristow, made the necessary cultures and roll-tubes. Whether the micro-organism in question stands in an ætiological relation to the disease or not, the fact remains of its constant presence in all of these cases, as shown by the following summary of the results obtained:

Of the entire series of eight cases, seven gave pure cultures of the *Bacterium commune coli*.

In one case the *Bacillus pyogenes fetidis* was obtained, in addition to the *Bacterium commune coli* (examination made by Dr. E. H. Wilson, pathologist to St. Mary's Hospital).

In four cases encysted sero-fibrinous deposits (encysted intraperitoneal suppurative peritonitis) were present.

In two cases appendical abscess existed.

In one case general sero-purulent peritonitis existed.

In one case no pus or serum was found. A periappendicitis and serous parietal appendicitis existed only; the mucous membrane lining the appendix was normal. No fecal matter was found in the interior of the tube. The cultures were made from a patch of lymph on the peritoneal surface of an adjoining portion of the cæcum, to which the tip of the appendix had become adherent. This culture gave pure *Bacterium commune coli*. Attempts to procure the micro-organisms from the sections of the wall of the appendix were unsuccessful, although more than a hundred sections were made and examined by Professor Van Cott and Dr. Wilson.

A word of comment upon the last observation. The entire absence of inflammatory conditions in the mucous membrane of the organ, together with the presence of an inflammation of the peritoneal covering and wall of the organ, which was most pronounced at the point where it rested against the cæcum, suggests a migration of the bacterium through the wall of the bowel itself, the appendix becoming infected from that direction.

GOLD IN THERAPY.*

By E. A. WOOD, M.D.,
PITTSBURGH, PA.

GOLD is one of the old remedies which have been crowded to the wall by the more brilliant achievements of modern pharmacy. It is safe to say that one half of the medical profession never prescribe gold; the large body of the other half use it occasionally, while a very small minority employ it constantly in the class of cases in which it is best suited.

Gold, practically, to the main body of the profession is a new remedy. From the company it has fallen in with of late, gold is open to suspicion, and whether it is a partner in the "Keeley cure" or not, many will be prejudiced against it. It would seem timely and just to drag the old drug from its dusty closet and tear it away from its bad company that we may learn what standing it really deserves in therapeutics.

What, then, is the pathological condition in which gold is especially indicated as a curative agent? Let us answer this question with as much precision as possible. If gold has a place in therapy, it must fill a special place, for it, like all other drugs, is no panacea. What is its place?

What say authorities in reply to this question? In view of its great age, it is astonishing how meager the literature. It is still more astonishing that until within a very recent period we had practically but one preparation of gold—the chloride of gold and sodium. That preparation to-day is the one given, and by it the standard of gold is rated as a curative agent. Gold is as old a remedy as mercury, and yet gold to-day is almost unplaced in therapeutics. The compounds of mercury are a legion, its history is voluminous, and its therapy accurately known and established. We know more perhaps about mercury than about any other drug; we know less of gold than of most drugs.

Authorities agree in declaring that the chloride of gold and sodium is an alterative, behaving very like mercuric chloride. No author gives gold a very wide range in therapy; no one attempts to name the exact pathological condition in which it is best indicated and most efficient; and nearly all who have written on gold in therapy, whether designedly or not, succeed in "damning it with faint praise." Syphilis is one of the diseases in which it is commended, some say in the secondary lesions, others that it is best suited in the tertiary form. The praise given to gold in syphilis is not high—certainly not so loud as that given to mercury. It is said to be aphrodisiac and emmenagogue. *Tabes dorsualis* and cirrhosis of the liver, lungs, and kidneys are said to be cured by gold. Some praise it in diseases of the glandular system, especially in disease of the glands of the stomach and intestines, as it increases the appetite and promotes secretion, digestion, and nutrition. It is said to give force to brain action, courage to the despondent, hope to the hypochondriac, and content to the melancholic. All speak of it as affecting the gums without

salivation, and that it produces an eruption of the skin and gold fever. The latter I have never seen.

That is the sum and substance of what therapeutists say of the chloride of gold and sodium. But there are three questions which are still unanswered: 1. Is the chloride of gold and sodium more efficient in the lesions named than any other drug? 2. Is gold in therapy limited to the one double salt? 3. What is the special pathological condition in which gold is most efficient as a curative agent?

Leaving out the first question for the present, I shall undertake to answer the other two as observation and experience have taught me.

My more immediate purpose is to direct your attention to some preparations of gold other than that of the chloride of gold and sodium, samples of which are before you.

The first preparation I shall notice, and the one with which I am best acquainted, through prescribing it for the past seven months in the place of the double salt, is the liquor auri et arsenii bromidi. The successful combining of gold with bromine, mercury, arsenic, and other metals is due to the indefatigable labors of Dr. W. F. Barclay, of Pittsburgh, who persevered in the face of the decree of some chemist that such compounds are impossible. There stands the liquid bromide of gold and arsenic. There stands the liquor of gold and mercuric bromide. Here are other preparations of gold combined with other metals. As there is no filtering employed in the manufacturing of these liquors, every atom of the metals must be present. The two liquors are, as you see, beautifully red and transparent, elegant as the garnet fluids in the show bottles of a druggist's window. I am not sure that it will not fade under exposure to light, but I know that after months' standing not a shadow of sediment mars its complete transparency. It is almost tasteless. The dose—ten drops—contains one thirty-second of a grain of gold and one sixteenth of a grain of bromide of arsenic. The mercuric bromide of gold contains one thirty-second of a grain each of gold and bromide of mercury to ten drops, which is the dose. Each preparation is pleasant to take, is more readily absorbed than the chloride of gold and sodium, and, in my experience, is more assimilable and active than the double salt. Of course the gold is modified and its action intensified by the combination with other metals. It is probable that gold will readily combine with all other metals used in therapeutics.

The class of diseases in which I have found gold to be peculiarly efficient, and in which it seems to be especially curative above all other drugs, is that class in which *sclerosis* is the chief factor. In naming *sclerosis* as a class, I am perhaps taking undue liberty with the nomenclature of the pathologist, since the term *sclerosis* is generally understood to mean induration of the tissues of the brain and spinal cord. Literally, it is proper to apply the term *sclerosis* to any organ or tissue in which induration is the factor. When we marshal such pathological conditions into a class, we shall find that *sclerosis* has a wider and, it seems to me, a more significant meaning than has been hitherto attached to the word and the lesions it names. It would seem as though we have reduced therapeutics to an

* Read before the Mississippi Valley Medical Association at its nineteenth annual meeting.

exact science when, instead of a name, we establish an exact pathological condition, with the remedy most efficient in removing that condition. That is the exactitude we have in gold as a special curative agent in all forms of sclerosis. Cirrhosis of the liver, interstitial nephritis, atheroma and its associate, calcareous degeneration of the arteries; the circumscribed induration following embolism or blood-clot in the brain tissue, senility and its train of decrepitudes—for what is old age but a general sclerosis?—all belong to the class I have named. Cirrhosis of the lungs, certain forms of consumption—fibroid consumption, miliary tuberculosis, and especially that form of consumption in which masses of lymph become organized in the lymphatics of the lungs as we see the process in the glands of the neck and called adenitis. Without naming all the lesions that may be classified under the head sclerosis, I will state as my belief, founded on an experience of twenty years, that gold is far more efficient in them all than any other drug I know of. I desire to say in addition that the liquid preparations of gold as combined with bromine, arsenic, iodine, and mercury are as much superior to the chloride of gold and sodium as quinine is superior to the crude Peruvian bark.

In addition to its efficiency in the scleroses it would seem as though gold, at least the liquor auri et arsenii bromidi, exercises a power as a tonic and nutrient to the nervous system, especially to the nervous systems of those who have advanced to fifty and beyond. May it not be that in cases of neurotic diseases of the aged there is a sclerosis? Certain it is that gold is not so efficacious in functional nervous ailments of the young. It is just to remember, too, that the association of gold with bromine and arsenic may have very much to do with its curative powers. But for all that gold and its preparations is the medicine for those in middle life and in old age. It stimulates the brain, incites a flow of spirits, gives sleep to the sleepless, courage to the despondent, and intensifies sexual desire and power. Gold should maintain physical vigor and prolong life even if taken when there is no disease except the inherited tendency to decay before reaching the Biblical limit of life.

In presenting a few cases taken from my clinical day-book I beg leave to remark that I appreciate incredulity, and with that thought before me I am guarded in my statements, feeling that a modest conservatism will be tolerated by you, whereas you would smile at and ignore the vivid praises of the enthusiast.

E. H., aged fifty-seven years, roofer; temperate, with good heredity and void of syphilis or any cachexia. Had complained of what he was told was rheumatism of the knee joints since February, 1892. Visits to the seashore and Mount Clements, together with medication by various physicians, did not arrest the disease, which grew steadily worse. On the 14th of May last I saw him with Dr. Barclay. His knees were swollen, stiff, and painful, preventing rest or sleep. He preferred to have his legs amputated rather than endure his agony. We diagnosed the case as arthritis deformans, and put him on the liquor auri et arsenii bromidi. In six weeks' time he pronounced himself cured, the pain and stiffness were gone, and the swelling was very much reduced. He still remains well up to date.

R. E. M., aged forty-five years. Heredity good. Having treated him for a year for locomotor ataxia by suspension, ergot, and other usual remedies, I placed him on the liquor of gold last July. He sleeps better, his appetite is improved, he is not so despondent, the girdle pain and the pain in his feet are very much abated, but there is no improvement in the coordination. He is still taking the gold.

C. T., periodical dram drinker. Took the gold two weeks, at the end of which time there were ulcers in the mouth and the teeth in the lower jaw were loosened.

M. Mc., aged fifty-two years. Heredity good. Very fond of women and noted for his sexual powers and endurance. He had suffered for eighteen months with neuralgia of the left trifacial nerve. He had tried various forms of treatment, among others that of having the sound teeth extracted from the left lower jaw, but without relief. Speaking was painful, mastication impossible, and swallowing of liquids agonizing. He was haggard with pain and loss of sleep. In spite of his protest, I treated him for syphilis by giving him mercury and the iodide of potassium. He improved very considerably, but the pain persisted, though to a slight degree, and grew worse on stopping the mercury. In June last I put him on the mercuric bromide of gold, with rapid improvement, and he pronounces himself cured. He still takes the gold occasionally.

I have administered the bromide of gold and mercury in two cases of iritis with evident advantage.

Two cases of fibroid consumption, with cavities, both the result of neglected pneumonitis, are astonishingly improving under the use of the bromide of gold and arsenic internally and the inhalations of papoid glycerole by the atomizer.

One case of pneumokoniosis, "grinders' consumption," had resisted treatment for four years, during which the patient lost in weight, while cough and expectoration increased. In July I put him on the bromide of gold and arsenic with papoid inhalations. September 27th, coughs a little on rising in the morning; expectoration no longer black. Gained fifteen pounds in weight.

One case of miliary tuberculosis, in which the pulse was 130, temperature 101° F., respiration 30, is rapidly improving on the gold.

Two cases of diabetes have improved under the use of the gold, one of them so much so that he was accepted last August as a good risk by one of the foremost life insurance companies. In both cases I gave codeine at the beginning of the treatment, but left it off and continued with the gold.

A case of adenitis, with enormous enlargement of the left side of the neck, is being rapidly cured by the bromide of gold and arsenic.

Does gold ever fail to cure? Yes, if given in cases unsuited for it. But in the scleroses, while it may fail, it will accomplish more cures than any other remedy.

The following cases in which the liquor auri et arsenii bromidi was used are contributed by Dr. W. F. Barclay, of Pittsburgh:

J. C. K., aged seven years and a half, family history good. Had convulsions for over five years, sometimes as many as five epileptic convulsions in a day; could not talk; had an idiotic expression; the saliva continually dribbled from his mouth; had an inordinate appetite, and constipation of the bowels. This

case was the first one in which I prescribed liquor auri et arsenii bromidi, five drops, three times a day, in water. About February 15th I began the treatment, and about March 1st he had a convulsion that lasted for about twelve hours, since which time he has had no convulsions. Continued the use of the medicine right along with no alteration, except to increase the dose to ten drops. Saw him on September 28th and find that he seemed entirely well; his mind is clear, his speech is natural, the saliva does not dribble from his mouth, his appetite is normal, and his bowels are regular. His aunt informs me that his memory is good and that he learns rapidly.

Miss S., aged forty-one years, family history good. Had neuritis with partial hemiplegia first about five years ago; has been better and worse during the time since until June 1st, when she was referred to my care for treatment by Dr. F. Le Moyné. She was unable to walk and suffered considerable pain along the spine and in her right arm and leg. Prescribed liquor auri et arsenii bromidi, ten drops, three times a day, in water. She has continued the treatment until the present time, and reports herself entirely well.

Mrs. S., aged forty-two years, family history good, menstruates regularly, has rheumatoid arthritis, and the joints of the fingers, wrists, elbows, and knees are ankylosed. Was first affected fifteen years ago, and has been unable to walk for over four years. Saw her for the first time on 21st of July; prescribed liquor auri et arsenii bromidi, ten drops, three times a day, in water. She has been under treatment now for over two months, and the ankylosis is entirely removed from the joints, and the bony deposits have been almost entirely removed. She is still under treatment, and is making a rapid recovery.

Mr. W. B. G., aged twenty-eight years, family history good. Was injured over two years ago by being caught in an elevator. Had fracture of two ribs on the left side, with slight pulmonary hæmorrhage. Has suffered more or less ever since. Six months ago had pain in the anterior and posterior parts of the chest, with difficulty in breathing. For over two years, when he exerted himself, had sharp, lancinating pains in his lungs, could not sleep at night, and had night-sweats with chills. Saw him on July 21st. Temperature, 108°; pulsations per minute, 130; skin dry and hot; respirations, 42 a minute. Had dry, subcrepitant râles over both lungs; dullness over both lungs. Prescribed liquor auri et arsenii bromidi, ten drops daily, in water.

September 27th.—Temperature, 99°; pulsation, 96; respirations, 24; still coughs some at night. He has gained ten pounds, and everything indicates that he is making a rapid recovery. Directed to continue treatment.

Mr. B., aged thirty-six years, had sciatica (left side), was quite lame, and suffered intense pain over sciatic notch, down the limb, over entire region of sciatic nerve. Prescribed liquor auri et arsenii bromidi, ten drops, three times a day, in water. After the third day he began to improve, and in three weeks had made a complete recovery.

The Public Health Section of the New York Academy of Medicine.—The first meeting of the season was held on Tuesday evening, the 10th inst., under the chairmanship of Dr. S. T. Armstrong. Mr. Ernest Hart, of London, read a forcibly written paper in which he elaborated the English idea of the worthlessness of quarantine, especially in the case of cholera, but admitted that in the United States there might be circumstances existing that justified a quarantine system.

Change of Address.—Dr. H. D. White, from Nutley, N. J., to Rutherford, N. J.

AN INQUIRY INTO THE ÆTIOLOGY OF MENTAL DISTURBANCES FOLLOWING OPERATIONS UPON THE FEMALE PELVIC ORGANS.*

By GEORGE H. ROHÉ, M.D.,

PRESIDENT OF THE
AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNÆCOLOGISTS;
SUPERINTENDENT OF THE MARYLAND HOSPITAL FOR THE INSANE,
CATONSVILLE, MD.

THE occurrence of insanity as a sequel of surgical operations has long been known. The more transitory forms of mental aberration, termed traumatic or nervous delirium, are recognized by all surgeons, although probably less frequently seen since the general adoption of aseptic methods in surgery. Within the past few years especial attention has been drawn to insanity following operations upon the female generative organs, and by some this occasional occurrence of mental disturbance has been held to be a contraindication to the performance of such operations. It has been maintained that insanity follows removal of the uterine appendages with especial frequency, and that therefore the possibility of this unfortunate complication should demand our particular attention before subjecting a patient to operation.

Struck by the frequent more or less positive references in the recent literature to insanity following gynæcological operations, and the rarity of personal contact with this condition, I ventured, a little over a year ago, to send a circular letter to the medical officers of all the institutions for the insane in the United States and British America requesting information upon this subject.

Replies to this circular were received from nearly all those addressed, and, to my surprise, returns of only twenty-five such cases occurring in the last ten years were obtained. While it is probable that some cases were missed through defective records in the institutions, it appears that some were reported as having become insane through the operation who were insane before it was done. Indeed, the histories furnished me show that in some cases the operation was done with a view of a beneficial effect upon insanity already existing.

It is probable that the cases reported to me represent a large proportion of those in whom the mental aberration was of a persistent character, and included few, if any, of those transitory forms more aptly characterized as delirium rather than true insanity.

The further history of these twenty-five patients as reported to me showed that nine were discharged from the hospitals—seven recovered and two improved. Four died and twelve remained under treatment. The discharges numbered thirty-six per cent., the deaths sixteen per cent., and the patients remaining in hospitals—some better, some stationary, some worse—forty-eight per cent. I shall return to the consideration of these figures presently.

The details of a number of the cases of mental disturbance following gynæcological operations leave much to be desired on the score of fullness and accuracy. In perhaps the majority of instances the reporter considers it sufficient

* Read before the Section in Gynecology and Abdominal Surgery of the First Pan-American Medical Congress.

to state that "insanity" followed the operation. However, enough is known to warrant the conclusion that several forms of mental disturbance, agreeing in the main with certain prominent clinical varieties of insanity, are met with as such post-operative sequels, but there is no special and distinctive form of post-operative psychosis.

There can be little doubt that in persons with emotional instability the shock of a grave operation may produce transitory delirium, or even more persistent mental aberration. The frequency of the so-called "transitory mania" at the moment of the completion of the second stage of labor is evidence that intense pain, combined with high nervous tension, is capable of producing it. The delirium attending severe injuries—"traumatic delirium"—may also in most cases perhaps be ranged with the cases of mental aberration from shock. Those cases of post-operative delirium or psychosis following immediately after the operation may, I think, be classed in this category. That other factors may concur in the production of this form of psychosis—*e. g.*, anxiety, worry, and the like—is probable. Ahlfeld reports a case of violent mania following the introduction of a speculum, and Kiernan one consequent on the passage of a catheter in a man. In a small number of the reported cases no other essential factor than the shock and anxiety can be traced. From this form the patient usually recovers.

A second class of post-operative insanity would appear to be due to the absorption of poisonous agents used before, during, or after the operation. It is now generally accepted that the acute mental disturbances, mostly hallucinatory in character, following operations upon the eye are due to the use of atropine and similar drugs. It is not improbable that some of the post-febrile psychoses are attributable to a similar cause. I have recently had under my care in the Maryland Hospital for the Insane a case of acute hallucinatory mania following rheumatism, in which I believed the beginning of the attack could be traced to heavy dosing with salicylates. The withdrawal of the medicine was followed by rapid recovery.

These cases of drug poisoning with pronounced symptoms of mental disturbance are probably not so very rare as sequelæ of grave surgical operations, particularly where extensive use is made of chemical antiseptics during the operation or in the after-treatment. The excessive use of opium, quinine, and other anodynes and antipyretics may with good reason be charged with some of the cases of post-operative insanity. I am of opinion that the rare cases of mental disturbance following the administration of anesthetics may properly be ranged under the same caption. One reason for this view is that in the large majority of these cases the symptoms are transitory and recovery promptly follows under appropriate treatment, the chief feature of which must be the withdrawal and elimination of the toxic agent.

A third class of cases of post-operative insanity I believe to be due to the absorption of septic materials from the wound or surface exposed during the operation. A study of reported cases shows that the insanity in most instances develops several days after the operation and is

usually of the clinical variety termed by some writers "acute confusional insanity." The prominent symptoms are insomnia, restlessness, emotional instability, sometimes sudden, violent outbreaks, followed by incoherence, variable hallucinations, especially of vision, and sometimes delusions of grandeur or persecution. In most cases there are symptoms of fever, and usually marked implication of the physical powers. The pulse is rapid and weak, the temperature elevated, the tongue dry and red, and there is, usually, refusal of food. Exhaustion of mind and body rapidly intervenes, and the patient sinks into a state of muttering delirium, coupled with great bodily weakness. The name "typhomania" is a fairly accurate designation for many of these cases. Essentially the condition is an exhaustion-psychosis due primarily to septic intoxication or septic infection. That the affection termed by writers "acute delirium," "delirium grave," etc., is generally a septic psychosis, as maintained by J. H. Lloyd, is extremely probable. This view will explain a considerable proportion of cases of post-operative insanity following upon gynecological operations. Professor Le Dentu has reported a number of cases coming under his personal observation. There were no essential differences between the acute cases following gynecological and those following other operations. This writer collected sixty-eight cases of post-operative insanity—thirty-eight following operations upon the female sexual organs and thirty developing subsequent to general operations.* Generally, he says, the mental disturbance begins from the second to the fifth day, although in some cases not until the twentieth or even later. He discusses the possible causes of post-operative insanity but does not offer a solution of the problem. Dr. Bantock, in referring to a case of "hysterical mania" following four or five days after a hysterectomy, says there was "considerable tumefaction of the mammae to account for the disturbance."

Excluding the cases due to shock, nervous strain, exhaustion, and drug intoxication, which generally appear within the first twenty-four hours, it is probable that the majority if not all the cases of post-operative insanity coming on within the first week are septic in origin. Puerperal insanity is coming to be regarded as essentially a septic psychosis, and in this large and well-studied class of mental disturbances we have the closest analogy to most cases of post-operative insanity. It is possible that some of these acute cases following removal of the uterus or appendages are due to the sudden induction of the menopause, for so acute an observer as Krafft-Ebing considers the onset of the climacteric as a cause of acute delirium. I am inclined to the opinion, however, that the fourth class of cases—namely, those coming on several weeks or months after the operation, and which are usually more persistent—may be attributed especially to this ætiological factor.

These may be regarded as essentially cases of climacteric insanity. The clinical form in which the psychosis

* Out of 185 cases collected by Sears (*Boston Medical and Surgical Journal*, June 29, 1893), only 43, or 23.2 per cent., followed operations upon the uterus or ovaries. Insanity follows operations on the eye more frequently than upon the female sexual organs.

manifests itself is the same as occurs in the majority of cases of climacteric insanity—namely, melancholia. It pursues a similar clinical course, and recovery follows in about the same percentage of cases.

In about four per cent. of all women admitted to insane hospitals the insanity is attributed to the menopause. Out of three thousand and forty-seven women admitted to the State hospitals in New York during three years, six hundred and sixty-six were between forty and fifty years of age. If we compare the total number of cases attributed to the climacteric to the total admissions at the climacteric age, we find the proportion of climacteric insanity to all insanity in women at the same age as one to five. Climacteric insanity, then, is not so very rare, and it should not surprise us to find a considerable number of cases among women in whom the menopause has been artificially induced. Indeed, when we consider the frequency of mental symptoms in the normal menopause, extended as it is usually over a period of several years, one is forced to expect marked psychical changes in the menopause induced by operation, where all the changes are sudden, violent, and abnormal.

Kisch states expressly that psychical disturbances at the climacteric period are more likely to occur in women of excitable nervous system and in women in whom the menopause appeared suddenly.

The records of cases of insanity following operations upon the female sexual organs are neither sufficiently large nor sufficiently exact to enable us to draw definite conclusions as to their actual causation. I believe, however, it would facilitate the study of the cases if they were more fully reported, and if some attempt were made to classify them as in this paper. The surgeon or gynecologist, in the majority of instances, simply reports that in a certain number of cases insanity—or perhaps he differentiates into mania and melancholia—followed his operations. The time of beginning of attack, the clinical features, the duration, and termination are generally omitted as unessential points. I am strongly inclined to the view that, in the great majority of cases of more or less persistent insanity following an operation upon the female sexual organs—comprising removal of the ovaries or uterus—the cause of the insanity is the induced climacteric, and that in most of these women the insanity would have been developed during the menopause, whether occurring normally or artificially induced. As a basis of this view, I call attention to the comparatively small number of cases of persistent insanity following removal of the ovaries and tubes, the clinical form of insanity present in the greater number, and, finally, the percentage of mental recovery, which closely approximates the recovery rates from ordinary climacteric insanity.

Answers to Correspondents:

No. 412.—We think not.

No. 413.—This correspondent does not give us his name and address; consequently, we can not guide him to our reply in the usual way. Painful distention of the large intestine could undoubtedly be caused by the procedure described, and it is quite likely that the pain would be accompanied with nausea if not vomiting, but we do not think that the vomiting, if any occurred, would be caused mechanically by the inflation.

IS IT SAFE TO ANÆSTHETIZE PATIENTS SUFFERING FROM AORTIC INSUFFICIENCY?

WITH REPORTS OF TWO CASES.

By R. E. GIFFEN, M. D.,

STREIGN GENERAL, NATIONAL GUARD OF NEBRASKA;
SURGEON IN CHIEF, ST. ELIZABETH HOSPITAL, LINCOLN, NEBRASKA.

It is a maxim laid down by our predecessors, taught from generation to generation: "Do not give an anæsthetic when your patient is suffering from valvular heart disease." From that maxim I beg leave to dissent and say that in the majority of cases it is reasonably safe to give an anæsthetic.

What happens to the heart in aortic insufficiency? The aortic insufficiency is followed by compensating hypertrophy of the left ventricle. When this hypertrophy begets dilatation, then follows, sooner or later, (a) peripheral failure of the circulation (œdema), or (b) central failure of the circulation, and sometimes both. We now ask ourselves, What is the limit of this compensated hypertrophy? At what point can we safely give an anæsthetic? The muscular impulse (intensity) and the rapidity (time) determine arterial pressure. Arterial pressure and rhythm make up the heart's action. Arterial pressure must not overcome rhythm. By physical diagnosis we determine hypertrophy: (a) by palpation at the apex; (b) by auscultation, rapidity, and rhythm.

Now, so long as that rapidity does not disturb the rhythm—viz., first sound, second sound, and pause—within reasonable physiological limits, or, in other words, the arterial pressure, composed of the time (rapidity) and intensity (muscular impulse), does not overcome rhythm, then, to my mind, we are safe in administering an anæsthetic.

The effect of ether as the patient becomes narcotized is to lower the arterial pressure to such an extent that the rhythm and arterial pressure are more than ever in accord. Take the reports of cases of death under an anæsthetic and they will, in the majority of instances, read like this: "On examining the heart before administering the anæsthetic, it was found in a normal condition; no valvular disease could be determined." Now, if in these cases more attention had been paid to the rhythm of the heart and the arterial pressure, no doubt fewer cases would need be reported.

The following are two cases which came under my care, both of whom suffered from aortic insufficiency, together with their other ills calling for surgical interference.

CASE I.—Boy, eleven years of age, was admitted to St. Elizabeth Hospital suffering from necrosis of the left tibia of tubercular origin. This lad had an aortic insufficiency, but the rhythm and arterial pressure were in perfect accord. I placed him under ether, Dr. Britt administering the anæsthetic. He was under the effect of it for an hour and thirty minutes, as I had to remove the entire shaft of the bone. At first the arterial pressure was increased, but by the time he became completely narcotized it had decreased until it was in perfect accord with the rhythm of the heart. His recovery was uninterrupted and the wound healed perfectly.

CASE II.—Mrs. R. C., aged forty-two years, came to me suffering from a cystic tumor of the right ovary and small

fibroid of the uterus with profuse hæmorrhages until she was very anæmic. She also had an aortic insufficiency from which she had suffered for over twenty years. The pain and hæmorrhage caused her so much suffering that, to use her own words, she said: "Do something for me, for I am dying by inches; I can not endure another attack of bleeding, and this pain in my side is eating my life out. Yet I am told I can not take an anæsthetic on account of my heart disease. I am willing to stand it without taking anything if you will only give me the chance of being relieved by an operation."

Now, I ask, what would you do under the circumstances? I had my friend Dr. Tyndale examine the heart, and he agreed with me that the intensity of the impulse plus the rapidity of the heart's action still permitted the rhythm of the heart to be distinguished—viz., the sounds did not merge into one another. I waited no longer, but made up my mind to operate, and after giving the patient ten days' preparatory treatment by rest in bed and nourishing diet, I operated, assisted by Dr. Tyndale and Dr. Britt, Dr. Britt administering the anæsthetic. I removed the ovarian cyst, also the ovary and tube of the left side to check the hæmorrhage from a small fibroid of the uterus. She was under the anæsthetic, from the beginning to the finishing of the operation, forty-five minutes. The effect of the ether was the same as in the first case. At first the arterial pressure was increased, but as narcosis deepened the rhythm and arterial pressure harmonized perfectly. Her recovery was uninterrupted, and now, three months after the operation, she writes me as follows: "I am free from pain in my abdomen, but I have got my old heart yet, and as it thumps and pumps, sending out a pain here and there, it seems to say, 'The surgeon's knife cured your other pains, but I defy them all.'"

With the experience I have given above, I feel justified in saying, In the future let us give more attention to rhythm of the heart and arterial pressure than has been done heretofore.

Visiting Physicians to the Hospitals for Infectious Diseases.—At a recent meeting of the Board of Health of the Health Department it was resolved that the board should appoint six attending physicians to the hospitals of that department, each to serve six months of the year, three being on duty at one time at each hospital. These attending physicians, when on duty, shall be required to visit the hospitals on at least two days of each week. Each physician when on duty may visit the hospitals daily. The attending physicians are to be required to conform on all occasions to such regulations as may be prescribed by the board of health, such as those relating to the wearing of gowns within the wards, disinfecting the hands on leaving the wards, the hours for visiting, the wards to be visited, etc. The board is to appoint one interne to serve in each hospital of the department for the term of three months, these internes to be chosen by the board from among recent graduates from approved medical colleges after an examination by the attending physicians, and their successors are to be appointed in like manner. The duties of the internes are to be such as usually pertain to the office of senior assistants in other hospitals, and they are to be at all times subject to the orders of the resident physician. The attending physicians and the internes are to serve without pay, except that the latter may reside within the hospitals if the resources of the hospitals permit of it.

The Medical Society of the County of Albany, N. Y.—The special order for the semi-annual meeting, on Tuesday, the 10th inst., was an address by the vice-president, Dr. Howard Van Rensselaer.

NEW YORK, SATURDAY, OCTOBER 14, 1893.

MOVABLE KIDNEY.

The *Lancet* for June 17th reports the Cavendish Lecture for 1893, by Dr. Morris, on the subject of movable kidney and its treatment by nephrorrhaphy. The lecturer would preserve the terms "misplaced kidney" and "displaced kidney" to denote the condition in which the kidney is permanently out of its normal position, and thinks that the word "movable" is alone sufficient to embrace all cases in which the kidney is so loosely attached as to shift from its normal place, but can be made to return to that place by some movement of the body or of the abdominal organs, or by the surgeon's hand. Dr. Morris justifies this comparatively simple classification by showing, first, that even the most motile of kidneys—those, for example, that float quite up to the anterior abdominal wall—may cause very little pain or other subjective symptoms, and have no mesonephron; secondly, that some of the very painful cases and those marked by frequent recurrences—those most likely to be mistaken for renal calculus—are hardly to be detected by clinical examination. It is only recently, or since surgical exploration of the kidney has come into vogue, that this form of dislocation has been shown to exist as a cause of very severe symptoms. These explorations have been undertaken, in not a few instances, in the belief that renal calculus would be found; but the movable kidney has been found and has been treated by a successful nephrorrhaphy. Errors of diagnosis have been made so often, in respect to movable abdominal tumors of various kinds, that doubts have been entertained as to movable kidney. Mr. Lawson Tait is quoted as affirming that some time ago he had knowledge of thirteen supposed cases of this infection, of which seven had proved to be gall-bladder cases—cases in which that viscus was enlarged by dropsy or by calculus or by both.

The relief afforded to those patients in whose cases the symptoms have been intense by the operation of merely stitching the kidney to the parietes of the loin has been incapable of being forgotten by any surgeon who has been permitted to follow up their histories. The most gratifying curative results of nephrorrhaphy have been noted when the sutures have been made to pass into the renal substance; the loose fibro-cellular capsule is shortened and stitched also to the muscle and fascia of the loin. Tuffier remarked, at the Surgical Congress in Paris, that in every case of nephrorrhaphy under his notice, provided the operation had been clearly indicated, it had accomplished a perfect result.

It can not be maintained that the life of the patient is directly threatened by motility of the kidney, but it is indi-

rectly in serious danger by reason of the changes wrought upon that organ by interference with the patency of its ureter and by compression of its vessels and nerves, possibly ending in suppurative or dropsical changes. These remoter results, along with the possibly prolonged period of ill-health and distress, may be pointed out whenever the surgeon is called upon to give advice as to an operation for either movable kidney or renal calculus.

It may be added that Dr. Edebohls, of New York, has recently improved the technique of nephrorrhaphy by the use of a cylindrical air cushion on which the patient's abdomen rests; the patient lies on the operating table face downward, instead of being in the Sims posture, as preferred by the majority of surgeons. This air cushion is eight inches wide and a foot long. It is inflated by means of a valve and key similar to that used with the football. The force of gravity and the resistance of the air cushion combine to throw the kidney well up to the line of the lumbar incision, so that the surgeon has full access to the entire organ and can palpate it, split its capsule, and otherwise prepare it for the suturing in a thorough manner.

MINOR PARAGRAPHS.

THE FULL CORRECTION OF MYOPIA.

DR. H. L. JENCKS, of Galena, Illinois, writes to us as follows: Dr. Edward Jackson, in the September number of *The American Journal of the Medical Sciences*, says: "It is, however, certain that on the part of a considerable number of ophthalmologists there is a disposition to avoid the giving of a full correction for myopia, or a timidity about it that keeps them from giving such lenses for constant use, or induces the advice to use the glasses as little as possible. This timidity is abundantly evidenced in ophthalmic literature and in the practice of colleagues, and was formerly largely shared by myself. It is to aid in showing that such timidity is mistaken and harmful that I bring forward my clinical experience in this matter. This expression of opinion as to the value of full correction is essentially the same as that advocated by Hartridge in his recent work *Refraction of the Eye*, page 150, where he says: 'My own opinion is that every case requires treating on its own merits; very many myopes wear their full correction constantly with comfort and, if not with benefit to the eye, most certainly without injury, while other myopes will occasionally be found who suffer from asthenopia when using their full correction for near vision.' It would thus seem from these two eminent authorities that in suitable cases the full correcting glasses should be constantly worn. In practice, however, many exceptions will have to be made to this rule."

MIKA'S OPERATION.

THE *Lyon médical* for September 24th contains an excerpt from *La Médecine moderne* on a bizarre surgical operation that is practiced by the aboriginal Australians. It consists in opening the inferior portion of the urethral canal near the scrotum. The wound is kept open until cicatrization produces a fistula. The operation is performed for the purpose of permitting of coitus and insuring relative sterility. In one Australian tribe M. Mikuko-Maclaya has counted three hundred men so operated on, while only three or four had the urethra intact. These

latter males were the most magnificent specimens of the race. M. Gazorowski recalls the fact that the aborigines of Santo Domingo practiced a similar operation on horses in the eighteenth century, so as to preserve all their vigor without the power of procreation. Sterility so produced is evidently only relative, for sperm deposited at the entrance of the vagina sometimes suffices to fecundate.

FRENCH PUNISHMENT FOR SANITARY DELINQUENCY.

IN France drastic measures are imposed on civil officials that are remiss in attending to the sanitation of their communities. The *Medical Week* for September 29th states that the mayor of a provincial town was recently suspended from his functions because no sanitary measures had been adopted at the outbreak of an epidemic to prevent the propagation of the disease, which was allowed to spread among the population for more than ten days before an attempt was made by the municipal authorities to comply with the advice of the medical man in charge and with the instructions of the government, by taking the necessary steps to stay the epidemic's progress; also because of the delay in the adoption of the precautionary measures recommended by the physicians sent by the government.

SPECIAL CARE FOR TUBERCULOUS PATIENTS.

THE *Medical Week* for September 29th states that, by a recent decision of the Hungarian Minister of Commerce, special care for phthical patients will be attached to all passenger trains between Buda-Pesth and Gleichenberg during the season at the latter place.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 10, 1893:

DISEASES.	Week ending Oct. 8.		Week ending Oct. 10.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	0	0
Typhoid fever.....	16	8	59	11
Scarlet fever.....	36	0	58	3
Cerebro-spinal meningitis....	1	1	3	3
Measles.....	32	5	53	2
Diphtheria.....	118	27	112	34
Small-pox.....	7	11	13	2

The Tri-State Medical Society.—A partial list of papers to be read at the fifth annual meeting, to be held in Chattanooga, Tennessee, on Tuesday, Wednesday, and Thursday of next week, under the presidency of Dr. Richard Douglas, of Nashville, has been issued, and includes the following titles:

Membranous Croup, with a Report of Cases treated with Tracheotomy, by Dr. R. M. Harbin, of Calhoun, Ga.; Intubation, by Dr. Max Thorne, of Cincinnati; The Treatment of Stone in the Cystic Duct, by Dr. W. E. B. Davis, of Birmingham, Ala.; Cholecystotomy, by Dr. Paul F. Eve, of Nashville; The Symptoms and Pathology of Fractures about the Elbow, by Dr. J. B. Murfree, of Murfreesboro, Tenn.; The Treatment and Prognosis of Fractures about the Elbow, by Dr. Willis F. Westmoreland, of Atlanta; The Action of the Galvanic Current on the Uterine Tissue, by Dr. H. Berlin, of Chattanooga; The Pathology of the Sequelæ of Purulent Inflammation of the Middle Ear, by Dr. T. Hilliard Wood, of Nashville; The Treatment of the Sequelæ of Purulent Inflammation of the Middle

Ear, by Dr. G. C. Sayage, of Nashville; The Significance of Albumin in the Urine in Pregnancy, by Dr. E. T. Camp, of Gadsden, Ala.; Serous or Watery Discharges during Gestation; their Source and Significance, by Dr. J. R. Rathmell, of Chattanooga; Tuberculosis on the Cumberland Mountains, by Dr. L. P. Barbour, of Tracy City, Tenn.; The Symptoms and Treatment of Gastritis, by Dr. G. T. Prince, of Whiteside, Tenn.; The Treatment of Varicocele, by Dr. J. W. Handly, of Nashville; The Treatment of Pyrexia, by Dr. J. A. Witherspoon, of Columbia, Tenn.; Recent Observation of Croupous Pneumonia, with Special Reference to Prophylaxis and Treatment, by Dr. R. M. Cunningham, of Birmingham, Ala.; Nasopharyngeal Adenoids, by Dr. E. L. Jones, of Chattanooga; The Ætiology, Pathology, and Prevention of Ophthalmia Neonatorum, by Dr. L. B. Graddy, of Nashville; The Treatment of Ophthalmia Neonatorum, by Dr. B. F. Travis, of Chattanooga; The Treatment of Puerperal Mastitis, by Dr. J. W. Russey, of Chattanooga; Disease of the Female Bladder, by Dr. J. C. Le Grand, of Anniston, Ala.; The Treatment of Psoriasis at Hot Springs, Ark., with Report of Cases, by Dr. J. Cabell Minor, of Hot Springs, Ark.; The Treatment of the Omentum in Hernia Operations, by Dr. G. A. Baxter, of Chattanooga; Report of the Psychical Science Congress, Chicago, August, 1893, by Dr. John E. Purdon, of Cullman, Ala.; The Elastic Dressing applied to Incomplete Ankylosis of the Knee, by Dr. C. W. Barrier, of Columbus, Ga.; Medical Ethics, by Dr. J. B. Cowan, of Tullahoma, Tenn.; Tubercular Peritonitis, by Dr. T. J. Crofford, of Memphis; Movable Kidney, by Dr. J. B. S. Holmes, of Rome, Ga.; The Pathology and Treatment of Gout, by Dr. W. C. Townes, of Chattanooga; and the president's address on The Responsibilities of the Abdominal Surgeon.

The late Dr. William B. Towles.—The University of Virginia has issued the following memorial:

"William B. Towles, late professor of anatomy and materia medica in the University of Virginia, was born March 7, 1847, at Columbia, Fluvanna County, Va.; entered this university as a student of medicine, October 1, 1867; and was graduated with the degree of doctor of medicine in June, 1869. On October 1, 1872, he returned to the service of the university as demonstrator of anatomy, and on the death of the revered and lamented Dr. John Staige Davis in 1885 was appointed his successor. He died September 15, 1893, upon the opening day of the seventieth session of the university, after an illness of a few hours. His one and twenty years of service form an epoch in the teaching of anatomy in this university and in America. The accuracy and abundance of his knowledge, the ardor and luminousness of his exposition, his skill in selecting and his felicity in expressing the salient truths of his science, conquered the confidence of his students, roused their interest and attention, and powerfully impressed their memories. In his intercourse with both colleagues and pupils he was frank, bold, and direct. Loyal to his friends and generous to the verge of profusion, indulgent to the frailties of youth and inexperience, but governed always by the highest sentiment of honor, he attracted the love of his pupils and the regard of his equals, and maintained from all the respect due to his robust intelligence, his manly nature, and his warm heart. His friends and colleagues in the faculty of the University of Virginia do therefore resolve:

"1. That they mourn the death of their late associate both as a personal bereavement and a public loss, and desire hereby to put on record their sense of his unsurpassed powers as a teacher and his noble qualities of mind and heart.

"2. That they extend to his afflicted family their profound sympathy in the dispensation of Providence which has taken

from them brother, husband, and father, and invoke for them those celestial consolations which alone are able to alleviate their grief.

"3. That these resolutions be spread upon the minutes, and that the chairman of the faculty be requested to transmit a copy to the family, and to cause them to be published in the Richmond and Charlottesville papers."

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 24 to October 7, 1893:

By direction of the Secretary of War, leave of absence for four months, on surgeon's certificate of disability, is granted TOWN, FRANCIS L., Lieutenant Colonel and Deputy Surgeon General.

CROSBY, WILLIAM D., Captain and Assistant Surgeon, is, by direction of the Secretary of War, granted leave of absence for three months.

WOODHULL, ALFRED A., and GIRAUD, ALFRED C., Majors and Surgeons, are detailed as delegates to represent the Medical Department of the Army at the annual meeting of the American Public Health Association, to be held at Chicago, Ill., from the 9th to the 14th of October, 1893.

Society Meetings for the Coming Week:

MONDAY, October 16th: New York County Medical Association; New York Academy of Medicine (Section in Ophthalmology and Otolaryngology); Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, October 17th: Tri-State Medical Society (first day—Chattanooga); New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Ogdensburg, N. Y., Medical Association; Medical Societies of the Counties of Kings, St. Lawrence (semi-annual), and Westchester (White Plains), N. Y.; Hunterdon, N. J., County Medical Society (Flemington); Baltimore Academy of Medicine.

WEDNESDAY, October 18th: Tri-State Medical Society (second day); Northwestern Medical and Surgical Society of New York (private); Harlem Medical Association of the City of New York; Medico-legal Society, New York; New York Academy of Medicine (Section in Public Health and Hygiene); New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society.

THURSDAY, October 19th: Tri-State Medical Society (third day); New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, October 20th: New York Academy of Medicine (Section in Orthopaedic Surgery); Baltimore Clinical Society; Chicago Gynaecological Society.

SATURDAY, October 21st: Clinical Society of the New York Post-graduate Medical School and Hospital.

Letters to the Editor.

A DISTINGUISHED ENGLISH VISITOR ON THE AMERICAN MEDICAL PROFESSION.

NEW YORK, October 12, 1893.

To the Editor of the New York Medical Journal:

SIR: Dr. Hammond's furious philippic is an incident which would be unworthy of notice but for the hospitality accorded

to it in your columns. I can not allow it to obscure even as a dirt spot upon the object-glass my retrospection of the three long and happy months passed in the United States.

I have enjoyed since June the pleasure of a series of friendly and courteous receptions by the leaders of the medical profession in the centers of medical education and activity in this great country, in conference, on subjects of professional organization, State medicine, and public hygiene. On each occasion, of the addresses which I have been privileged to give by invitation before large professional audiences at the American Medical Association, at the Association of Medical Editors at Milwaukee, the Chicago Medical Society, the Pan-American Congress, and the State Medical Association of New York, the opinions and views which I have ventured to express on subjects, such as water-borne cholera, medical editing, and medical code, in its relations to professional and public interests, etc., have been received with plaudits of unusual warmth. They have been emphasized by overwhelmingly kind expressions of approval from representative men on the spot and subsequently at Boston, Philadelphia, Baltimore, Cincinnati, Detroit, and other cities which I have visited with the Pan-American delegation. Dr. Hammond affects to fear that I may have hurt the feelings of Dr. Pepper and other eminent friends, and of the medical profession of Chicago, but it is precisely from them that I have received the warmest expression of approval. The distinguished president of the Pan-American Congress personally congratulated me after the delivery of my address, on the tact and delicacy with which, he was pleased to say, that thorny subject had been handled, expressly observing that not a word had been said to which reasonable objection could be made. I did not mention condurango, cerebrine, or Columbian chemicals; and I meant no disrespect to the equator. This outrageous outburst of injured innocence and wounded modesty appears to me, therefore, as I understand it does to others, comical but unimportant.

I have received more numerous, more enthusiastic and grateful indorsements of the views expressed by me in the Washington Congress than of any other of my utterances on this soil, warmly and universally as they have been applauded—far beyond their merits, no doubt, but with the gracious and widespread cordiality which makes my visit to America one of the most delightful memories of my life. This general approbation and unvarying courtesy are only accentuated by the critical fury and inhospitable rudeness of your present correspondent.

Let me now take this last opportunity, since I am leaving these hospitable shores to-morrow, of expressing once more the delight with which I have enjoyed this opportunity of making the personal acquaintance of such great numbers of my American colleagues.

Let me record my deep sense of the high honor which they have everywhere done me and my gratification at their assurances that my visit has not been without usefulness. Let me add the expression of my respect and admiration of the marvelous growth and development of medical skill and education and of the great medical institutions in all parts of this vast country.

I bear away with me many treasured friendships and innumerable assurances of friendly esteem, which I hope will long be continued. I carry with me to my English home associations and recollections which will always bind me in gratitude and affection to the great English-speaking profession on this side of the Atlantic, whose brotherhood we all, in Great Britain, so highly prize, and with which, now for many long weeks, I have been privileged to be in close, happy, and never-to-be-forgotten communion.

ERNEST HART.

Proceedings of Societies.

FIRST PAN-AMERICAN MEDICAL CONGRESS.

Held in Washington on Tuesday, Wednesday, Thursday, and Friday, September 5, 6, 7, and 8, 1893.

SECTION IN GENERAL SURGERY.

(Concluded from page 415.)

Orthopædic Apparatus.—Dr. A. M. PHELPS, of New York, exhibited several mechanical appliances: (1) A hip-joint splint, giving absolute fixation and lateral traction, by the use of which cases recovered without angular deformity; (2) A powerful instrument for operating on clubfoot in the adult after subcutaneous tenotomy; and (3) A pure aluminium corset which attracted much favorable comment.

Homologous Ligature of Divided Arteries.—In a paper with this title Dr. T. H. MANLEY, of New York, dwelt upon the subject of the homologous ligation of arteries in amputation, with a consideration of the applicability and limitations of torsion as a hæmostatic agent. He had performed several experiments upon the arteries of the dog and had found that the ligation of the vessel with its own living walls was the ideal method when it was practicable. He varied the technique in different cases. In one class he would simply bisect the vessel and ligate the redundant slack. He had in this way succeeded in obturating the saphenous vein in man. But in large arteries he would recommend one of two plans: One was to cut the trunk into three loops and stuff one end into the open lumen of the vessel and tie the other two free ends over it. The other method was to divide the vessel into four loops—two lateral, one posterior, and one anterior. The antero-posterior should be first knotted and pressed into the vessel's open orifice and the two lateral loops should then be secured with a triple reef knot. The tissues should be opposed in an orderly manner before closing the wound. The speaker said that the principle of the procedure, if attempted in time and practicable, would have an extensive range of application. Already he had utilized this plan in hernia operations, obturating the inguinal and femoral canals with knots made up of living tissues.

Combined Internal and External Urethrotomy with Vesico-urethral Drainage in the Treatment of Multiple Urethral Stricture.—Dr. JUAN MARTINEZ DEL CAMPO, of Mexico, presented a contribution on this subject. He said that all the methods which had been recommended for the cure of multiple strictures of the urethra, of gonorrhœal origin, had not been followed by permanently curative results. This observation was applicable alike to cases treated by gradual dilatation or by internal or external urethrotomy. The author sought to prove that urethral and vesical drainage following upon internal and external urethrotomy gave better and more permanently curative results than any other method of treatment. His conclusions were based upon the consideration of eight hundred to a thousand cases of patients who had been kept under observation during a period of ten years. About one fourth of the cases were patients who had been operated upon by this method several years prior to the date of the author's paper. In these the urethra had been examined to ascertain the condition of the canal after a long post-operative period. In all it was found that no relapse had supervened. The permanent excellence of the result the author attributed to the effect of the drainage-tube or catheter which was allowed to remain *in situ* for some variable length of time, and which, by causing an acute suppurative urethritis, had a tendency to disintegrate or resolve the embryoplastic tissues which constituted the stricture. His general conclusions were: (1) Multiple

strictures of the urethra of gonorrhoeal origin represent a clinical condition which is very frequently of long duration. (2) This condition seriously compromises the integrity of the genito-urinary apparatus, and consequently is of more or less menace to life. (3) The various methods which have been hitherto practiced for cure are only palliative, because they are almost invariably followed by relapse. (4) The treatment which appears to be most satisfactory because of its more permanent results is the combined method of internal and external urethrotomy associated with vesico-urethral drainage.

Traumatism and Traumatic Aneurysms of the Vertebral Artery.—Dr. RUDOLPH MATAS, of New Orleans, read a paper on this subject. He said that the operative surgery of the vertebral artery might be truly said to be an acquisition of the latter part of this century. Up to 1860, few surgeons had given any personal attention to the subject. The names of Dietrich, Velpeau, Munzianze-Ypollito, Sédillot, Fréys, Chassaignac and Laudi, Respoli, Maisonneuve, and Barbieri would comprise a list of the important contributors, the majority of the leading contemporary teachers believing that the vertebral artery was of scarcely any practical interest to the surgeon, and barely mentioned it in their texts—A. Cooper, Lisfranc, Vidal, Malgaigne, Guérin, Béraud, and Follin being notable examples of this indifference.

In 1834, Sanson, in describing a fatal case of gunshot injury of the vertebral artery that had been attended at the Hôtel Dieu of Paris, said: "The vertebral artery can not be ligated on account of its great depth, nor compressed because of the osseous canal which protects it; it can still less be cauterized. The wounds of this vessel are beyond the resources of art" (*Traité des hémorrhagies traumatiques*, Paris, p. 352). And the classical teaching of the day agreed with him until 1858, when the accomplished Maisonneuve, assisted by Favrot, succeeded in ligating the vertebral artery in a case of gunshot wound of the neck.

Various methods for the systematic and typical ligation of the vertebral had been suggested by Dietrich, Respoli, Yppolito, Fréys, and Chassaignac, which had received the attention of Velpeau, but no one had yet given a demonstration of the practicability of the typical ligation of the vertebral until Andrew W. Smythe, of New Orleans, successfully performed the operation on July 8, 1864, with the view of cutting off the collateral circulation to a subclavian aneurysm through the circle of Willis. This was the patient Banks, on whom, several weeks previously, he had ligated the innominate artery with complete success for the first time in the history of surgery.

After Smythe's brilliant demonstration the operation immediately became one of the classical acquisitions of surgery, and the comparative facility and benignity of the double ligation has been shown (apart from traumatic or surgical conditions) by the numerous but ineffectual attempts made to cure epilepsy by the ligation of both vertebrals by Alexander, of Liverpool, Bernays, of St. Louis, and Chalot, of Toulouse, France.

It was the good fortune of the author to have brought to his clinic in the New Orleans Charity Hospital, on July 6, 1888, a young mulatto boy who was suffering with a traumatic aneurysm of the vertebral, resulting from a gunshot wound in the upper part of the neck. Upon examination, a traumatic aneurysm of the right vertebral artery was found which occupied the suboccipital triangle and involved the artery in the atlao-axoid space. The patient was at once put to bed and a three-pound weight applied directly over the tumor and held *in situ* with an elastic bandage round the forehead.

After four days, as little impression had been made upon the tumor by the pressure, two long electrolytic needles, connected with the negative pole of a galvanic battery, were introduced

as deeply as possible into the softest parts of the tumor, and the current furnished by twelve cells applied. This application lasted about an hour without any perceptible results. Two days later the tumor was incised and the sac extirpated, and the bleeding point plugged with small aseptic sponges, over which a thick packing of iodoform gauze was placed, a careful sublimate external dressing applied, and the whole firmly held in place by an elastic woven bandage wound over the forehead and neck. Eleven days after the operation the wound was entirely healed, and three weeks later the patient was discharged from the hospital entirely well. Eleven months afterward the patient had returned to the hospital with the wound cicatrized and entirely free from any aneurysmal lesion.

Injuries of the vertebral artery were, fortunately, of great rarity. A glance at the surgical anatomy of the vessel would at once remind us of the magnitude of the technical difficulties in the way of its atypical ligation, and of the errors of diagnosis to be incurred owing to the proximity of so many large arterial trunks. Furthermore, the unique termination of the vertebral artery in the cranial cavity—where, anastomosing directly with its fellow artery, it became continuous with the carotid system through the circle of Willis—would convince us of the unreliability of either proximate or distant ligation of this artery as a permanent means of controlling the blood supply of any aneurysmal tumor that might be situated between either one of its cervical extremes.

One of the initial difficulties usually presented by aneurysms of the cervical portion of the vertebral artery was that of differential diagnosis from similar tumors connected with the carotid and its branches. In forty-four and two thirds per cent. of the recorded traumatism of the vertebral artery hæmostasis was attempted by ligation of the carotid alone, or the carotid together with some other artery—inferior thyreoid (Maisonneuve), occipital (Fenger)—the error being recognized only *post operationem*.

After searching all the available literature, the author had succeeded in collecting fifty-three cases of lesions of the vertebral artery, which he had divided into three groups:

1. Endocranial aneurysms, eleven cases.
2. Extracranial or cervical aneurysms, twenty cases.
3. Wounds or lesions of the artery involving its surgical or extracranial portion, twenty-two cases.

Out of this total of fifty-three cases he found that forty-five had died in direct consequence of the lesion of the vertebral artery, or complicating circumstances associated with it.

The cases of endocranial aneurysm had resulted, with one exception, from the degenerative changes in the endocranial arteries, and these cases, without exception, had ended fatally.

Of the twenty cervical aneurysms, six had recovered, leaving a mortality of seventy per cent. for this class of injuries. These aneurysms, with one exception, were traumatic. The non-aneurysmal injuries, of which twenty-two were recorded, were, with the exception of three cases, the result of traumatism, chiefly stab, punctured, or gunshot wounds. Of these twenty-two cases, only two recovered, leaving a mortality of ninety per cent.

If we added the cases under Group 2 to the cases under Group 3 we would then have forty-one cases of wounds with a total mortality of 80.69 per cent., and with recoveries amounting to 19.31 per cent.

Upon investigation of the immediate causes of death in the forty-three tabulated cases, we could readily recognize five essential factors, which, in the order of their frequency and importance, were as follows: (1) hæmorrhage; (2) shock; (3) sepsis; (4) exhaustion; (5) cerebral complications.

A traumatic aneurysm of the vertebral artery occurred only

as a sequel to the original injury, but the clinical difference between a primary bleeding wound of this artery and the false aneurysm that might follow it was of sufficient practical interest in the treatment to justify a separate consideration of the two conditions. While the prognosis of traumatic aneurysm was very grave, the percentage of recoveries was greater than the primary bleeding injuries of this artery; in a tabulated record of twenty cases of traumatic aneurysm, six patients, or thirty per cent., had recovered, while in a collection of twenty-two cases of primary non-aneurysmal injuries, only two, or 9.2 per cent., had recovered.

The six successful cases were as follows:

1. Moebus, 1827. Treatment: Rest and local application of ice poultices.

2. Warren Stone, of New Orleans, 1849. Treatment: Opening of the sac and plugging of the wounded artery.

3. Kocher, Berne, 1872. Treatment: Incision of the sac and application of styptic plug into the orifice of the vertebral canal of the atlas.

4. Weir, of New York, 1884. Treatment: Digital and direct compression, rest.

5. Christian Fenger, of Chicago, 1881. Treatment: Ligation of common carotid and occipital, opening of the entire sac, ligation of the vertebral artery between the axis and atlas. In this case the vertebral artery was as large as the internal carotid.

6. Rudolph Matas, of New Orleans, 1888. Treatment: Rest, cold, pressure, electrolysis, incision, extirpation of sac, plugging of bleeding point.

The author had arrived, therefore, at the following conclusions:

A. *Treatment of Traumatic Aneurysms*.—1. There are certain favorable cases (Moebus, Weir) of traumatic aneurysm in the upper and more superficial portion of the artery in which recovery is possible *without operative interference*; rest, direct compression, and cold being apparently sufficient to arrest the circulation in the tumor.

2. That in every case, when the danger of rupture of the sac is not immediate, good results may be expected, if only as adjuncts to future radical treatment, from the systematic application of cold, local and general rest, using for direct compression ice bags containing shot, which are easily adapted to the contour of the affected region.

3. That in the majority of cases the natural tendency of the aneurysm is to progress rapidly to a fatal termination in spite of the preceding measures, the sac usually rupturing in the direction of the weakest point—viz., the track of the wound that caused it.

4. But this tendency to spontaneous rupture is markedly favored by the increased tension caused by the ligation of the carotid trunks, so frequently and unfortunately done under the impression of a mistaken diagnosis.

5. That this deplorable result should always be avoided in case of doubt by a careful observation of the effects of temporary compression of the carotid upon the circulation of the tumor before applying the definitive ligature.

6. That in almost all cases but one (Fenger's case), in which a deliberate and prepared attempt has been made to ligate the artery in the aneurysmal region or at the bleeding point, the efforts of the operator have been frustrated by the copiousness of the hemorrhage, and temporary plugging of the bleeding spot and, at times, the more accurate plugging of the arterio-vertebral canal have been forced upon the surgeon as methods of necessity instead of methods of election.

7. That, fortunately, this method of plugging, when combined with free exposure of the bleeding region and clearing

out of the clots, has thus far given the most encouraging results, and that the more aseptic and non-irritating the material used in plugging, the greater the simplicity of the after-care of the case. Judging by the especially fortunate or excellent results which were obtained by Warren Stone, of New Orleans, in 1847, with plain charpie lint; J. Mason Warren, of Boston, with sponges; by King, of Hull, with oiled lint; by Küster, of Berlin, with iodoform gauze; by Simes, of Philadelphia, with plain lint, and my own experience with well-sterilized sponges re-enforced by iodoform gauze, it would not be necessary to resort to styptic plugs (as in Lücke's or Kocher's cases), which have a tendency to inflame a wound and render its aseptic management most difficult. In addition, as in the writer's case, small fragments of sterilized sponge, if they are used only in plugging the canals, have the advantage that they may be allowed to remain *permanently* in the wound, where they are incorporated as *grafts* by the living tissues.

8. That the use of coagulant injections is especially to be condemned, the perchloride of iron (as in Lücke's case) having proved most pernicious. Ergotin (Langenbeck) injected into the periphery of the sac may aid in effecting a cure, but it is exceedingly doubtful that this material will distinguish itself more favorably in this region than in the treatment of other aneurysms. While the newly isolated physiological fibrin ferments (Wright) may prove less irritating, they will be likewise open to objections from the mechanical standpoint (embolism). Possibly electrolysis and Macewen's method of securing the formation of white thrombi by "needling" may claim some success in the future, but this is very doubtful, and the most authorized opinion at present would point to—

9. The acceptance of the method of Antyllus, modified by the conditions of modern surgery, and the only reliable, if still dangerous, method of dealing with this always formidable condition, at least in the majority of cases. If this operation is decided upon, every preparation should be made to meet all emergencies. Saline infusion may be required, but a good supply of sterilized sponges, iodoform gauze, and long-handled strong hemostatic (hysterectomy) forceps will be most useful, the latter especially in grasping bleeding points, or in applying strong pressure to the deep and unusually rigid tissues in which they are found. The gouge, chisel, or "rongeur" forceps should not be forgotten; the rapid resection of a part of the transverse process may be required, in order to permanently secure the artery, though, usually, the plugging of the arterio-vertebral canal alone will be quite sufficient to accomplish permanent hæmostasis, and should always be attempted first, if only as a provisional measure, or in cases in which the exhausted condition of the patient will not permit more radical procedures.

When the aneurysm is well circumscribed, is high up in the neck, and ordinary local treatment has failed and the operator decides upon the method of Antyllus as a last resort, then it is justifiable to make an incision parallel with the anterior border of the sterno-mastoid, and, following the lines mapped out by Frays and Chassaing, reach the vertebral below the anterior tubercle of the sixth cervical transverse process and under the sheath of the carotid compress the vertebral before it enters the foramen, with the finger of an assistant. In that way the arterio-vertebral circulation will be temporarily arrested until the wounded artery has been definitely secured at the bottom of the aneurysmal cavity. By this procedure there will be much less traumatism inflicted on the weakened patient than if a formal ligation is attempted. In addition, the danger of secondary cerebral complication will be lessened.

10. In the extremely rare cases of idiopathic cervical aneu-

rysm, and in the circumscribed traumatic aneurysms that are situated high up in the posterior portion of the neck, and which would not be encroached upon by any of the classical incisions for the ligation of the vertebral artery at its origin, a ligation on the Hunterian principle might be attempted with some prospect of success, especially if cold, pressure, and rest were resorted to as adjuncts in the treatment. While the collateral flow from the circle of Willis is very rapidly re-established—more so even in the vertebral circuit than in that of the carotid—it is nevertheless possible that the contents of the sac may be completely coagulated before this collateral supply has been re-established.

In aneurysms that are situated lower in the neck, the Hunterian ligation, if applied by any of the classical incisions for securing the vertebral at its origin, will almost certainly end in an Antyllian operation, for it will be impossible to reach the trunk of the artery without involving the sac in the incision.

B. Treatment of Primary (Bleeding) Wounds.—1. In the management of bleeding wounds (non-aneurysmal) of the vertebral artery, the principles of treatment are practically the same as in those which guide the surgeon in the open or Antyllian method of attacking the traumatic aneurysms of this artery.

2. In some rare cases the nature of the injury is such that a direct attack on the bleeding point is practically impossible; this is notably true of those complicated gunshot injuries in which the missile has penetrated through the mouth and the blood is flowing into the pharyngeal space. In these cases there is usually an associated wound of one of the carotid branches, especially the internal carotid, and the hemorrhage is so violent that death takes place before any assistance can be rendered. The diagnosis can be attempted under these circumstances, and, as plugging through the mouth is impracticable, the only hope for the patient lies in the immediate but provisional control of both the common carotid and the vertebral artery of the corresponding side, with a view of cutting off the entire arterial supply from the injured region. This result can be obtained without much difficulty by rapidly exposing the carotid sheath at the point of election and passing a ligature round the artery, which is not to be closed, however, but should be transferred to an assistant, who can control the circulation of the artery by simply pulling on the loop. The operator then presses with his finger in the depth of the wound at a point just below the anterior tubercle of the sixth cervical vertebra, and in this way arrests the flow from the vertebral artery. A complete control of the two vessels is thereby obtained, the hemorrhage is arrested, and the diagnosis can be undertaken with more deliberation. The definitive ligature may then be applied to either one of the exposed arteries, or to both if necessary.

In cases complicated with an injury of the internal jugular high in the neck and communicating with the pharynx, the resources of surgery are reduced to a minimum. But then the traumatism is so great that the shock of the injury alone will often kill the patient almost instantaneously, and if this is not the case the bleeding will be so profuse that life will ebb out long before any efficient assistance can be rendered.

3. In the more common cases the difficulties and dangers are greatest in the lower cervical course of the artery before its entrance into the foramen of the sixth cervical vertebra, owing to the immediate proximity of vital structures, especially on the left side. Wounds of this portion are generally fatal before the surgeon is called upon to deal with them, owing to the rapidly lethal effects of associated hemorrhage from the carotid and subclavian arteries and corresponding veins. In the wounds of this and the remainder of the cervical portion of

the vertebral artery the fundamental maxim in the treatment of hemorrhage—viz., "to control the artery while bleeding and at the bleeding point"—imposes itself as a first duty. This control can only be effected by the methods previously indicated when dealing with traumatic aneurysm, and may be finally summarized in a general way as follows:

1. If allowed by the position of the wound, deep and strong pressure should be made by an assistant below the carotid tubercle, with a view of compressing the vertebral at this point.

2. The wound should be freely enlarged in order to more directly expose the artery.

3. Direct pressure with the finger in the wound should be applied to the bleeding point.

4. Pressure on the bleeding point with strong hemostatic (hysterectomy) forceps, holding a small sterilized sponge, or by actually clamping the bleeding point *en masse* as a substitute for the finger.

5. Denudation or exposure of the artery in the intertransverse space, or, if necessary, by biting with "rongeur" or gouging out the antero-external portion of the bony canal in which the artery is contained. This last procedure is perfectly practicable in any part of the vertebral canal, provided a free exposure of the transverse process is obtained and the bleeding be provisionally controlled by digital or forcipressure.

Epithelioma of the Tongue and its Treatment.—This was the subject of a paper by Dr. L. C. LANE, of San Francisco. The author accepted the view of those observers who asserted that epithelioma was the only form of malignant lingual neoplasm except those that might have reached the tongue by primary invasion of contiguous structures. Epithelioma had its origin deep in the epithelial elements, and, according to its site, might be divided into two classes—the excrecent and the internal or the interstitial. Each form might arise from a papilla, wart, nevus, or limited abrasion. In the excrecent or papillary species the growth was outward, tuberculated or wart-like prominences being isolated or forced into an uplifted plateau. The penetrating species commenced usually on the side of the tongue, the new-formed elements crowding upon and destroying as they invaded the deeper structures, finally reaching and opening blood-vessels of more or less magnitude. These metastatic processes were continued until the affection had no definite bounds.

The causation of epithelial cancer of the tongue was unknown, but certain agencies might be cited as promoting its evolution, such as calcareous incrustations on the inner face of the teeth, sharp points or edges of the teeth which continued to wound the borders of the tongue, and the habit of thrusting the tongue into an interstice between teeth. The use of tobacco was probably a causal agency, the disease being far more frequent in men than in women. Epithelioma of the tongue seldom appeared before the fortieth year of age. When allowed to run its course, lingual cancer completed its fatal work within fourteen months. Operative interference did not offer encouraging prospects, though probably as high as seventy-five per cent. of the patients attacked might be saved if the disease were seen in the primary stage and treated by intelligent surgery, but meddlesome ignorance too often monopolized the precious time during which the patient might be saved. The absence of metastatic glandular infection must be regarded as the *sine qua non* of safety. When intelligent management had stepped in and prolonged life, two years was usually the limit of time before death ensued. The author's paper considered at length the gross pathology, diagnosis, and treatment of lingual epitheliomatous growths, and contained ample bibliographical research with citations of cases.

The Mechanical Treatment of Osteo-arthritis of the Knee.—Dr. HENRY LING TAYLOR, of New York, described and demonstrated the mechanical procedures in the above condition. He said that osteo-arthritis of the knee, or "white swelling," was usually a tubercular process, beginning in an adjacent epiphysis or in the synovial membrane, and, if unchecked, finally involved most of the joint structures. It was accompanied by the usual symptoms of chronic joint inflammation, of which spasm and atrophy of the muscles acting upon the joint were practically the most important, as indicating most exactly the degree of joint irritation; and also by certain characteristic deformities at the knee—namely, flexion, eversion, abduction (*genu valgum*), and subluxation backward of the head of the tibia. The deformities were due to the mechanical conditions under which the spasmodically irritated thigh muscles acted. The general indication for treatment was to improve the nutrition of the patient, and thus insure a blood supply of good quality to the diseased area, facilitating the reparative process. One of the most gratifying results of proper mechanical treatment was the marked and speedy gain in general health and vigor. The local indications for treatment were to inaugurate and promote the process of repair at the site of disease, and to prevent or correct deformity, in order to restore, so far as possible, the functions of the joint. These local indications were met by mechanically providing conditions favoring the relaxation of the spasmodically contracted muscles, a normal local circulation, gradual correction of the deformity, and, later, the protected use of the joint. In the stage of irritation and disintegration strict local rest was enforced by the use of an apparatus giving counterextension and fixation, and for a month or two the patient was kept recumbent. When the local circulation and position of the limb had sufficiently improved, locomotion was permitted first with, subsequently without crutches, but always protected by the apparatus. After a considerable period of such enforced rest, during which the reparative process was completed, the neuro-muscular apparatus should be regulated and strengthened by allowing limited motion at the joint; last of all, the joint might be gradually trained to bear weight, as a preparation for discarding all treatment. The Dow supporting and protective apparatus with a lock-joint at the knee might be used to meet all these varied indications; the aim of the author, however, was not to advocate the use of any particular apparatus, but to point out the varying indications presented by the disease in its different stages, and that the elements of protection artificially supplied should vary to correspond. Protection from external and internal trauma with progressive replacement of distorted parts should be furnished at all stages—at first with enforced disuse, later with protected use, limited by the operator to meet the conditions present.

Dr. Taylor also demonstrated several other improved mechanical appliances interesting to the orthopedist.

Some Points in the Surgical Treatment of Appendicitis.

—Dr. AUGUSTUS P. CLARKE, of Cambridge, Mass., in a paper on this question, said that, from a careful study of the histories of cases coming under the writer's observation during a number of years past, and also from learning in many instances the final results of those cases, it was not unsafe to say that in every case in which there was reason to believe that the vermiform appendix was involved, though the symptoms at first might be mild or transient, the surgeon or medical attendant should be ready to institute measures against the occurrence of sudden surprises and unusual results. There was great probability in almost any event that the appendix, during an attack of inflammation, would become adherent to other parts in the immediate vicinity. In many cases, if not in the most, incision

should be made over the point of greatest tenderness; this corresponded to the McBurney point, which was midway between the umbilicus and the superior spinous process of the ilium, and in the right linea semilunaris. Such an incision would afford an opportunity for free drainage and for flushing the parts with warm carbolized water or with water of the temperature of 115° to 120° containing boric acid or other antiseptic agents that could safely be introduced into an abscess cavity. A liberal incision, when timely made over the tender part, had always yielded in the cases occurring in the author's practice an immediate and permanent result. In all cases after the incision had been made, the parts should be thoroughly explored; if the appendix was within easy reach it should be brought forward and then sewed off by means of sutures of aseptic kangaroo tendon. The cordwainer's stitch would be most convenient for accomplishing this. If, however, the appendix was bound down by firm adhesions, or if it could be found without much difficulty or without doing excessive violence to the cæcum or to other parts, it would be far better to allow it to remain, for its presence, when thus left, would not seriously interfere with the patient's recovery. In most cases when the mesentery or other parts had been sufficiently detached, the appendix should not be tied but should be clamped, and then sewed off by means of carbolized animal sutures; as soon as all hæmorrhage had been controlled the appendix might be incised about two centimetres from the cæcal tissue. In order to prevent adhesions of the stump or base of the pedicle to other structures, the peritoneal tissue in immediate vicinity of the margin of the incision should be closely approximated by a subperitoneal suture. The smaller-sized kangaroo tendon, rendered aseptic, should preferably be the material for such use. A thorough closure of the peritoneal surface of the wound thus effected would not only obviate the occurrence of agglutination of the parts, but would also help to prevent the escape into the peritonæum of aseptic matter that might gravitate toward this point, and thus preclude the occurrence of a fistulous tract. The entire wound should, as far as possible, be kept in an aseptic condition. Aristol and iodoform would be found to be excellent adjuvants in maintaining this condition of the tissues. The danger of the subsequent occurrence of hernia might be overcome by paying strict attention to the closure of the severed layers that had been divided in the operation; the peritonæum, the muscular tissue, the fascia, and the external integument should each be brought together separately. Carbolized animal sutures should be used for this purpose. Entire closure of the wound by first intention could be effected only in those cases in which the operation had been undertaken in the early stage of the attack. After the formation of an abscess complete union at first could not be expected to follow, because some method for facilitating drainage for a while would have to be employed. The different steps of an operation were much complicated when there was present an unusual abdominal distention; so also it would be in cases in which there was excessive or marked obesity. Trendelenburg's posture in this, as in all cases of abdominal section for intestinal affections, could not be overestimated. In those cases in which some means for drainage became necessary every detail in the treatment should receive the strictest attention, for if there should occur any hindrance to a free discharge of the exudation a risk of a dangerous sepsis to the organism would be incurred. In every such case of abdominal section, when a drainage-tube had been employed, the possibility of the occurrence of hernia should not be overlooked. In all cases, whether the drainage-tube had been required or not, a firm binder or a thorough bandaging should be employed; the patient for some weeks should be kept for the most part in the horizontal position. The question often arose,

Should the surgeon, when called upon in the later stages of a case, advise operative interference? In answer to this it might be remarked that our experience in such cases was favorable to the adoption of an exploratory incision. When an operation was undertaken in the later stages the patient must, of course, assume more risks, for the chances of recovery were much less than when an operation was attempted much earlier, though surgical measures at such late date might prevent the rupturing of an abscess into the peritoneal cavity; when there had been such a rupture, removal of the pus and cleansing of the parts might afford an opportunity for a retrograde process of the disease to take place. Nothing, therefore, but the occurrence of extreme collapse should weigh against the employment of operative measures. In those cases of appendicitis which had gone on to suppuration before operative measures have been undertaken there might occur secondary abscess in other portions of the abdominal cavity. An operation to insure relief must therefore embrace a course of procedure which would afford a free discharge to all accumulation of purulent exudation; it would sometimes be necessary to make a prolonged dissection at different parts and also to overcome adhesions of an unusual extent. Great care would also have to be exercised lest an opening be made into an adherent intestinal mass. In some instances portions of the epiploon might have become gangrenous; there might occur in the veins of the abdomen an inflammation that might extend outward to the other vascular tissue. In carrying out for these complications the necessary surgical treatment much judgment would have to be exercised and much precaution taken that the dissection or search be not prolonged beyond what might afterward prove to be a beneficial or safe proceeding.

Empyema and its Treatment.—Dr. CARL BECK, of New York, read a paper with this title, in which he said that he did not know of any other place where empyema was as prevalent as in New York city and its vicinity. During eleven years the author had treated one hundred and thirty-four cases of empyema by resection of one or more ribs. The first series, containing thirty-five cases, when he was strongly recommending resection even in children, had been published in New York on December 6, 1886 (*Med. Presse*). In reference to this publication he felt that he was entitled to some credit in having been the first surgeon who recommended resection not alone, as usually understood, for the purpose of having sufficient drainage, or of favoring the thorax to approach the pulmonary pleura, but for *enabling the surgeon to introduce his index finger and of making it possible to palpate the pleural walls*. This was the only procedure which with certainty showed the presence and allowed the immediate removal of lumps consisting of fibrinous or cheesy products attached to the pleura. (Nine among ten cases showed lumps of goose-egg size.) As long as we had no physical, mechanical, or speculative means to distinguish between this condition and a simple collection of liquid pus, or as long as we could not liquefy the lumps by the use of a dissolving injection first, aspiration and even incision were insufficient, and therefore not the correct surgical procedures.

Among the 134 patients, 48 were below three years, 56 between three and ten, 11 between ten and sixteen, and 19 were above this age; 14 had died (10 from tuberculosis), (9 were older than sixteen), 105 were simple acute cases, 29 were complicated. Among 5 double-sided cases, 4 patients recovered.

All the empyemata with offensive smell (4 cases) had ended fatally.

Average time of healing process, five weeks.

In the case of a baby six months old, recovery was perfect after six days.

Anæsthetics were administered only when the pulse was

strong. Generally caffeine was given before. Otherwise an ether spray was applied, this explaining why no accident happened during operation. As the diaphragm after evacuation always rose upward, he usually resected the sixth rib (never below). Through the anterior axillary line, under antiseptic precautions of course, he made an incision about three inches long which at once divided the periosteum. Then with a small curved elevator he lifted the periosteum from the rib; the instrument was then pushed underneath the rib from one to the opposite side, so that the rib was riding on it. A blunt hook retracted the tissues alongside the rib toward the axilla; one blade of bone-scissors was introduced below the rib, between hook and elevator, and the same cut through. Then the elevator was pushed toward the sternum, thus freeing the rib from the last fragments of adhering periosteum; the hook was inserted at the opposite edge of the wound and there the rib was divided with the scissors in the same manner. A piece long enough to allow the introduction of the finger sufficed. It was impossible to strike the intercostal artery during these manipulations. Through a small opening made in the pleura with a bistoury a Péan forceps was introduced and the pus slowly evacuated. A sponge was pressed against the opening from time to time to interrupt the stream to avoid too rapid an expansion of the lungs. The whole evacuation required at least twenty minutes' time. The finger was now introduced, and if lumps were found to be adherent to the pleural walls, they were wiped off with the index finger, or with a blunt spoon made for this purpose, similar to a spoon for stone in the bladder. Irrigation by a bichloride solution, 1 to 5,000, was mainly used for mechanical purposes—that was, to evacuate thoroughly. The pleura with four iodoform silk sutures was then stitched to the skin, forming a mouth (pleurostomia.) This covered the wound surface, prevented after-bleeding, and kept the opening large. Then iodoform powder was put into the cavity to reduce the secretions. The wound was then covered with iodoform gauze. The whole side was protected by a pasteboard-like piece of sterilized moss, which, after being slightly dipped into a solution, adapted itself to the shape of the body like a plaster-of-Paris dressing. A strip of rubber adhesive plaster kept it tight, so that no air could enter. During respiration it acted like an aspirating valve and absorbed at the same time. For the first few days the dressing of the diseased side surrounded the whole arm. After three days a rubber drainage-tube, of the size of a man's index finger, secured by two large safety-pins in the shape of a cross, was introduced. He had refrained from introducing it immediately after operation, since he had observed considerable bleeding and irritation. Undoubtedly the constant respiratory movement of the pleura caused irritation in the way of rubbing and pressing. It seemed that after the pleura became more accustomed to being exposed to the air they could bear irritation by a foreign body better. As the cavity was entirely emptied after the operation, there was no necessity for washing it out afterward. On an average, two weeks after the operation a smaller drain was introduced, which gradually was shortened. The patient had always to lie on the diseased side of his thorax and was lifted up every four hours by elevating his pelvis and legs in a vertical direction, so that the pus could flow out into the dressing. The latter had to be changed twice a day for the first week, later on once a day, and after two weeks only every second or third day. The thermometer was used as the indicator for the treatment. The author's experience led him to the conclusion that *simple empyema operated upon early* would only under extraordinary circumstances take an unfavorable issue. The diagnosis of empyema had to be made by the aspiratory needle, which, if there was much cheesy accumulation or a small cavity

had to be introduced quite often at different points. He found it useful, when he could not draw any pus, to push the wire through the needle, a procedure which sometimes made a trifle of pus appear on the end of the needle. He might add that he did not advise resection in sero-fibrinous exudations, as had been recommended lately, but he had in such cases successfully injected a ten-per-cent. iodoform glycerin mixture into the pleural cavity, having first aspirated.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Fifteenth Annual Congress, held in New York on Monday, Tuesday, and Wednesday, May 22, 23, and 24, 1893.

The President, DR. MORRIS J. ASCH, of New York, in the Chair.

The Withholding of Reports of Operations for the Relief of Cancer of the Throat.—DR. D. BRYSON DELAVAN, of New York, read a paper on this subject. (See page 428.)

DR. J. SOLIS-COHEN, of Philadelphia: I think we are very much indebted to Dr. Delavan for calling our attention to this subject. There are various reasons which prevent men from giving statistics of their operations. The operations usually take place in busy hospital wards, and after the surgeon has attained a certain eminence and does not longer wish to advertise himself he neglects to present these cases to the profession. He may make a memorandum, but he is busy with his work, puts away his notes and forgets about them. Even many successful cases of operation for carcinoma of the pharynx, tonsils, etc., have thus never been reported. A younger man, on the contrary, will report his cases because he wishes his friends to know that he is in the field, and is as successful in the long run as his colleagues. Another point is this: A surgeon often operates and the case turns out unsuccessfully on account of neglect of the after-treatment. Some surgeons, for instance, will operate in a severe case in the morning and leave the patient to the usual attendant or to an assistant, and go fishing in the afternoon, and of course such men do not like to acknowledge their neglect. The patient may recover; but again he may not, and I think a great many failures are due to this cause—lack of proper supervision by the operator of the subsequent management of the case. Another cause: After a man gets along in practice he loses much confidence in statistics. A practical man, while he knows the general trend of opinion, finds that he does best by studying his own cases. He may have performed a certain operation fifty or seventy-five times, and he will know or feel that in certain cases the operation will or will not prove successful, no matter what the general statistics may indicate. Therefore, if we depend too much on statistics, we are in danger of not looking sufficiently closely into the merits of each particular case. The success of an operation depends on a variety of things: the condition of the patient, his surroundings, his opportunities for after-treatment, the stage of the disease, etc. The statistics of such men as Billroth, Krause, Lange, and others, who keep accurate records of their cases, are of course very valuable. In this country hospital practice is different, too, from that abroad. There, physicians are often paid for their services, and certain duties are expected in consequence. The personal responsibility is greater. Here we are not paid for our work in the hospitals, and unless a case presents some peculiar features to which we desire to call the attention of the profession, we neglect it, just as we neglect a good many other things as we get older.

DR. DELAVAN: I admit that it is very difficult to get accurate statistics, but do not see how we can advance unless through the medium of just such material. It is desirable that each of the members of this association should try to do his

part toward stimulating his surgical friends to greater accuracy of detail in this matter. In the statistics of the last ten years, those of the last five years are less favorable than those of the preceding five. This is said to be due to the fact that during the first five years the operations were performed by distinguished surgeons, whereas in the last five years they have been done more generally. This should induce us to ascertain who the best surgeons are for this class of operations. It is not alone the operation itself which requires especial experience and skill. The after-treatment is an all-important matter, as Dr. Solis Cohen has well said, and upon it will often depend the success of the case. There are so many difficulties in the way of successful after-treatment, and such variety is presented in the special necessities of different individual cases, that the full reporting of every case would, for the present at least, be valuable and instructive. The outlook for many of these cases is so unfavorable that we can not emphasize too strongly the necessity for recognizing and for giving to the world any information which promises to be helpful, even in the slightest and most remote degree. It is in this spirit that I have brought the subject before you.

Arthritis Deformans of the Larynx.—DR. W. E. CASSELLBERRY, of Chicago, read a paper with this title. (See page 430.)

DR. W. K. SIMPSON, of New York: I think the diagnosis of arthritis deformans of the larynx, unless rheumatic manifestations exist in other parts of the body, is very difficult to make. This was impressed on my mind by a case which was under my care for a number of years. The patient was a woman with arthritis deformans confined to the larynx. She was subject to acute exacerbations of the disease. The larynx was very much inflamed, and sufficient obstruction was produced to necessitate intubation. She did well under this treatment, and had no further trouble for a number of months. Her second attack was more purely of the arthritis deformans type. There was no acute inflammation of the larynx; on the contrary, it was very pale; the cords were adducted, and there was a swelling of the crico-arytenoid joints, necessitating intubation a second time. In consequence she has a permanent ankylosis of the right arytenoid articulation, and very little movement on the other side. The woman was thirty-five years of age, and gave a history of syphilis and rheumatism.

The question comes up why the breathing was so much interfered with in the case narrated by Dr. Casselberry. I think in these cases there is a certain amount of submucous thickening below the cords.

In another case that was under my care I think the trouble was congenital. The patient was a young man, aged twenty years; he comes from a phthisical family. There was marked hypertrophy of the tonsils, and very decided deformity at the right crico-arytenoid articulation. When phonation is attempted, the arytenoids override somewhat. In this case the rheumatic tendency may be thrown out. The young man came to me and inquired whether he could use his larynx in singing. I told him it was impossible to decide until he tried it. He did so, and found it impossible to continue for any length of time without suffering from hoarseness due to exacerbations of his condition.

DR. CASSELLBERRY: I regret somewhat that the discussion or criticism of my paper has not been more general, because I recognize the fact that its title and substance are unique. The relief which was afforded is readily explained by the fact that at the height of the seizure it was an acute exacerbation of a previously existing chronic arthritis. It is well known how small an aperture a patient can breathe through comfortably after he gets accustomed to it. One observes this in cases of stenosis of the larynx. We also know how quickly an attack of acute laryngitis, superimposed on this chronic condition, will

cause violent dyspnea. Such seems to have occurred in this case. In arthritis deformans or rheumatic states the patients are subject to acute exacerbations. It was so in other joints throughout the body of this patient; it was so in the larynx. The symptoms would remain quiescent for a time, and then the patient would be seized with an acute exacerbation.

Concerning the title of my paper, I endeavored to make it explicit that the name "arthritis deformans" was adopted, instead of rheumatoid arthritis or rheumatic gout, which names are the ones commonly employed, because of the position which has been taken by pathologists in general that this disease is entirely distinct from either rheumatism or gout; that it is not rheumatism, that it is not gout, and therefore entitled to an independent name. The laryngeal complication of arthritis deformans consequently is not correctly described as rheumatic or gouty, but should accord with the nomenclature of the general disease, and is best described under the name of "arthritis deformans of the larynx," as expressive of its independence of rheumatism or gout.

Laryngitis Hiemalis. Rhinitis Œdematosa.—Dr. J. C. MULHALL, of St. Louis, read a paper on each of these subjects. (See pages 431 and 432.)

Dr. E. L. SHURLY, of Detroit: In regard to the first part of Dr. Mulhall's paper, I think we shall all agree that the condition he refers to is a systemic affection, and is the result of what is known as "a cold," which may be due to malaria or some other bodily disturbance. It is a very common occurrence in emphysematous patients, or in the plethoric or obese. I have never regarded it as a local affection. I think it depends principally upon some irritation of the ganglionic nervous system.

In regard to the second part of Dr. Mulhall's paper, he has described purely laryngitis sicca, which, however, is not always accompanied by pharyngitis sicca. This is not particularly a disease of cold weather, for I have frequently observed it at all seasons, in young girls, especially in those who are taking music lessons; although seeming to be tolerably healthy, it will be found often that they have some derangement of the function of menstruation, or that they have been "crowded" by their work, or are too ambitious, seeking to do more than their nervous system can sustain. In these cases I have not found any signs of atrophic rhinitis—excepting once or twice. It always occurred to me that such were cases of "laryngitis sicca," and that the ætiology must be looked for in the general system. Local treatment does some good undoubtedly, but not very much. The restriction of work, and the use internally of phosphorus and iron, seems to do these cases the most good. Of all the local treatment, I have obtained the best results from the use of a mild spray composed of oil of tar and alcohol, and electricity.

Dr. J. WEIGERT, of Brooklyn: I quite agree with the previous speakers as regards the constitutional origin of rhinitis Œdematosa, but at the same time it is a very rare thing, in my experience, to find this condition as purely the result of systemic disturbance, without some thickening of the nasal mucous membrane—some chronic rhinitis. Of course, the principal factor is the constitutional one; but when this thickening does exist, I have found that the best thing to do is to apply the canter to the inferior and middle turbinated bodies. In other cases I do not think the local treatment is of any value.

Dr. C. C. RICE, of New York: I do not think that here in New York we are familiar with the variety of laryngitis that Dr. Mulhall speaks of—that is, laryngitis characterized by collections of dry scabby secretions in the larynx and independent of pharyngeal disorder. In my experience, such disease of the larynx is always secondary to nasal or pharyngeal trouble. I can not recall a single case in which I did not find some mor-

bid condition of the mucous membrane higher up, beginning in the post-nasal space and running down the posterior wall of the pharynx. The few exceptions to this general rule are those cases in which the disturbance in the larynx is out of proportion to that in the pharynx, owing to some peculiar exciting cause, such as is to be found in singers, actors, etc., who use their voices in an unusual way. We know that the exacerbations in pharyngitis sicca and atrophic rhinitis are more likely to occur in cold weather. Laryngeal disorder, independent of some pharyngeal disorder, I am not familiar with.

Dr. CASSELBERRY: I would support Dr. Mulhall's position regarding the independence of what he has termed "winter laryngitis." I can hardly accept that term, however, inasmuch as I have observed the same form of disease in Chicago at various times during the year. It has impressed me as a laryngitis sicca acuta—an acute form of laryngitis with deficient secretion. I have often been astonished at the amount of dry incrustation and the absolute aphonia at one moment and the comparatively good voice the next moment when the crusts were cleared off. I have observed it in patients who were comparatively free from nasal or pharyngeal disease. I say comparatively free because we rarely see anybody in Chicago who is absolutely free from nasal and pharyngeal disease. The patients referred to are those who suffer from what we call an acute cold, in which the brunt of the disease is borne by the larynx; usually, however, there is also acute pharyngitis and rhinitis of mild form, which is not the cause of the laryngitis in this instance, but simply an unimportant accompaniment.

Concerning rhinitis Œdematosa, I was struck with the aptness of this title, and believe the cases reported by Dr. Mulhall are closely allied to that Œdematous condition of the nasal mucosa which is associated with and which seems to underlie the formation of nasal myxomata, and which is also seen in association with bronchial asthma. Not that the asthma is caused by the nasal Œdema, but that the two conditions are simultaneous manifestations of the same vaso-motor paresis affecting the blood-vessels of the mucosa of both the nasal and bronchial tracts. I have observed also what may be an allied but not identical neurosis affecting the anterior ends of the inferior turbinated bodies. The particular case which is recalled to my mind consisted of a protrusion of the tissue of one or both inferior turbinated bodies—at times actually a half to three quarters of an inch outside the anterior nasal orifice. The membrane would protrude and again collapse by spells; when collapsed, being entirely withdrawn into the nasal chamber.

Dr. H. L. SWAIN, of New Haven: The gentlemen who have spoken about laryngitis hiemalis have come from soot-laden cities. In New Haven we also have something which corresponds to the description given by Dr. Mulhall. We burn no soft coal, therefore that can not be considered as a factor in the production of the disease. I myself am a victim of it, so I can speak with considerable authority. So far as my experience goes, I have never had it except in cold weather; I have no pharyngitis sicca; I have slight hypertrophic rhinitis. This past winter I had two patients similarly afflicted at the same time as myself. They were both university men, who were using their voices considerably in delivering lectures, and at that time I myself was straining my voice delivering lectures and attending to a heavy line of professional work. The weather was intensely cold. I am therefore inclined to agree with Dr. Mulhall in his remarks as to the ætiology of the disease. I have had this same trouble at the same season during three consecutive years, and am inclined to believe that it is partly due to overwork.

In regard to rhinitis Œdematosa, we also have such cases in New Haven, and I have this year been attending a patient who

has these attacks in connection with bronchial asthma. At the times when the swelling takes place the bronchial asthma is of extreme severity, and I have been unable to control it by treatment applied to the nose. I have frequently made appointments with this patient to cauterize the nose, and then found nothing there to cauterize. At other times I have cauterized existing hypertrophies, removed the spurs from the septum and tried to improve the general health, with a view to correcting the disturbance of the sympathetic nerves, and still the patient is subject to these same attacks if she goes out of town. While she remains in New Haven she does not have them, but when she comes to New York she invariably has an attack of oedematous swelling upon returning home.

Dr. F. I. KNIGHT, of Boston: I certainly can say that in the vicinity of Boston we meet with the form of laryngitis which Dr. Mulhall has described. The patients return to the hospital with the same complaint winter after winter, and I have met with them also in private practice. Of course, the form of laryngitis which is associated with atrophic disease above is more common, and that we are all familiar with, but I certainly have seen a good many cases where there was no evidence at all of anything in the nose or pharynx which could be considered a factor in the production of the disease. In the hospital cases, in my experience, there has been a good deal of thickening of the anterior surface of the posterior wall, where the secretion is prone to collect and dry, as well as on the cords, and here it furnishes an additional mechanical obstruction to the proper movements of the cords, producing aphonia in the morning, and later in the day simply more or less hoarseness. These cases occur in the winter; I do not know that I have ever seen a case in summer. The treatment that I have found most effective in these chronic, constantly recurring cases is a solution of silver nitrate, applied in varying strengths, and gradually increased to thirty or forty grains to the ounce. This has seemed more effective than any other treatment, and I have tried almost everything.

Dr. A. B. THRASHER, of Cincinnati: I think I can say, without an undue exhibition of personal pride, that I practice in a city the atmosphere of which is more filled with coal dust than any other in America. I have never seen this particular form of laryngitis unaccompanied by an inflammatory condition of the pharyngeal mucosa and also of the nasal mucous membrane. Almost invariably, in my experience, it has been produced by either an extension of the inflammation downward, or by an improper condition of the air when it enters the larynx, on account of mouth-breathing, or an inflamed condition of the upper air tract. Nor have I noticed it to be confined especially to cold weather. I have seen this condition of laryngitis sicca present in summer.

Dr. J. W. GLEITSMANN, of New York: I must confess that I am inclined to take the same position as Dr. Rice in the discussion of this subject, as I have never seen cases of laryngitis sicca without coexisting symptoms in the throat and nose. I have seen patients who have been under treatment for some time, and in whom the pharyngeal and nasal symptoms have disappeared, leaving behind that condition of the larynx which has been described here, and which approaches the condition of laryngitis sicca.

Dr. J. W. FARLOW, of Boston: I have never seen a case where there was not a dry condition of the nose, the nose being more open than it should be, and the morbid condition extending down into the larynx and pharynx. The hardened secretions are attached to one or both cords. I have had good success in treating these cases with oily preparations, which I consider fully as efficient as silver nitrate; at any rate, they should follow the use of the nitrate.

Dr. W. C. GLASGOW, of St. Louis: I did not hear the first part of Dr. Mulhall's paper, but from what I heard it struck me that the cases he reported were similar to the cases reported to this association by me at the Detroit meeting in 1885. Those cases were characterized by intense swelling, with great pallor of the mucous membrane and a discharge of livid serum. One case was typical. The patient was a man; he suffered with facial neuralgia and had the condition of the nose described above. The mucous membrane was white, discharging freely, and the nasal obstruction was marked. When the mucous membrane was touched, there was a fresh discharge of serum. There was intense pain on that side of the face. The nasal disturbance subsided without treatment when the neuralgia disappeared. I regarded this condition simply as a neurosis, and entirely independent of any local lesion. There was also in another case a certain amount of nasal thickening, with retention of secretion, which seemed to keep up the irritation, but, on the whole, I believed it to be strictly a neurosis. I also think that in bronchial asthma we have a similar condition of the bronchial mucous membrane that we have in the nasal membrane in these cases—a vaso-motor spasm of the arterioles of the mucous membrane, and an exudation into the membrane of the fluids of the blood. I base this theory upon the action of the nitrites and other drugs which give relief in asthma, and which are known as arterial dilators. In the treatment of these cases cocaine was absolutely useless. The only remedies that seemed to relieve them were the preparations of belladonna, morphine, and the nitrites.

Dr. S. W. LANGMAID, of Boston: One word about the cases of laryngitis with incrustation of the cords. I can not help thinking that the presence or absence of these crusts depends somewhat on the locality in which the patient resides. During my summer term at the hospital these cases are not common, and in private practice I have found them very uncommon. I agree with the gentleman—Dr. Shurly, I think it was—who said that he had often seen this condition in young girls.

Dr. MULHALL: The discussion in regard to winter laryngitis reveals two camps. It occurs to me that certain members have never seen the disease. Every one present is familiar with the ordinary laryngitis sicca, complicated with trouble in the upper air passages. It seems to me that the personal testimony of a member of this association, who is himself afflicted with this winter laryngitis, exactly as I have described it, should convince the gentlemen that such a disease exists, especially as other members have also observed this form of laryngitis, without any affection of the upper air passages. I accept the suggestion made by Dr. Casselberry to add the word "acute" to the title. This disease, as the doctor said, might be better called acute winter laryngitis, because it seldom becomes chronic. It is a condition which rapidly gets better, especially under vigorous treatment. The disease disappears when the patient removes to a warm climate. The form of laryngitis referred to by Dr. Rice and Dr. Gleitsmann is the one described in all text-books—the one with which we are all familiar. That form which I present has never to my knowledge been described. I mention the smoke not as a causative agent in producing this form of laryngitis, but as producing the color of the crusts. The crusts were black simply from the inhalation of soot. I do not think that an atmosphere laden with coal dust has anything to do with the production of the disease.

Some of the gentlemen confounded rhinitis oedematosa with another group of vaso-motor disturbances, rhinorrhœa, with chronic thickening of the nasal mucous membrane. In the condition I described the swelling is purely oedematous; it has nothing to do with the intumescent form mentioned by Dr. Casselberry. I have never read Dr. Glasgow's paper to which

he referred, and do not know whether these cases are the same as those he described. Before leaving St. Louis I mentioned this subject to him in his office that I expected to read a paper on this subject, and he did not call my attention to his paper. From Dr. Thrasher's remarks I infer that he has not seen the class of cases to which I refer. They are exceedingly uncommon.

(To be continued.)

Miscellany.

The Discovery of the Anæsthetic Property of Ether.—

The October number of the *Virginia Medical Monthly* contains a remarkably well written article by Dr. Luther B. Grandy, the editor of the *Atlanta Medical and Surgical Journal*, sustaining the late Dr. Crawford W. Long's title to be known as the discoverer of ether anæsthesia. The following is the greater portion of Dr. Grandy's article:

"The true story of the first discovery of anæsthesia and of the circumstances connected therewith has not yet been told in print. Reliable history is never written by the generation which makes it. The generation which inaugurated the era of painless surgery has passed away; the participants in the long and bitter controversy over the question of priority have disappeared; and those of us who have since come upon the scene may now undertake to gather up the data relating to that great discovery, unaffected by favor and unbiassed by prejudice.

"The claims of Dr. Long to the honor of this discovery have been presented to the world by no less a champion than the distinguished J. Marion Sims himself. Dr. Sims's article appeared in the *Virginia Medical Monthly*, May, 1877; but it was hurriedly prepared on the eve of the author's departure for Europe, after an imperfect correspondence with Dr. Long and others, and contains some errors which the latter was anxious to have corrected. Upon these errors the claim has been raised that to another belongs a large part of the credit which the profession has accorded to Dr. Long.

"My own interest in this matter is due to an accident, which need not be related here. For the purposes of this paper I have been kindly furnished by the Long family with all the documents, correspondence, and certificates which had been gathered by Dr. Long in support of his claim to priority. I have had access to papers which Dr. Sims never saw. I have talked with some persons, and corresponded with others, who were personally acquainted with Long and his work in 1842, and am thus able to present some features of the case hitherto unpublished.

"The paper of Dr. Sims had its origin in an interview with Dr. P. A. Wilhite, of Anderson, S. C., October, 1876. Dr. Wilhite was witnessing one of Dr. Sims's operations in New York, and remarked that he 'assisted at the first operation ever performed under the influence of ether.' He then said that this operation was done by Dr. C. W. Long, of Jefferson, Ga., in March, 1842, while the patient was completely anesthetized with sulphuric ether. He 'presumed that he (Wilhite) was the first person who ever profoundly etherized any one,' and then related how he had playfully and unintentionally etherized a negro boy to the point of complete anæsthesia in the fall of 1839, near Athens, Ga. Sims's article makes it appear that four young men—Wilhite, Groves, and two Longs (relatives of Dr. Long)—were medical students in the office of Dr. Long prior to the events of 1842, and the author states that Wilhite's

story about the negro boy encouraged Long in his belief that ether might be used for surgical purposes. These statements of Sims's, based entirely upon information received from Wilhite himself, have caused the friends of the latter to magnify his relation with this matter, and even to enter a claim in his behalf.*

"As a matter of fact, Wilhite did not become a student of Dr. Long in his office until the latter had done several operations under ether. After graduating at the University of Pennsylvania, in 1839, Dr. Long spent one year in New York city, and returned to Jefferson, Ga., to practice medicine in the summer of 1840. It is not likely that he would have attracted four students to his office at the age of twenty-five. He had no students under him until after his marriage, August, 1842, and the first was his cousin, D. J. Long. In another place in Sims's paper Wilhite is made to say that he assisted Dr. Long in operations 'under the influence of ether in 1843 and 1844, while he was a student in Dr. Long's office.' Wilhite was not even present at Dr. Long's first operations. In the entire volume of papers before me relating to Long's first two or three operations, including the sworn statements of parties who were actually present, no mention is anywhere made of Wilhite. Moreover not until years afterward does it seem to have occurred to Wilhite himself that he had any connection whatever with the discovery of anæsthesia. When Dr. Long's case was being argued before Congress, he obtained from Wilhite a certificate (February 4, 1854) with these words: 'I entered the office of Dr. C. W. Long, of Jefferson, Ga., in October, 1844, where I continued about eighteen months. Not long after I entered his office, and not later than 1845, I heard the said Dr. Long speak of having used sulphuric ether by inhalation, to prevent pain in surgical operations, he referring to a period of time before I entered his office.' The remainder of the certificate states that he (Wilhite) had heard others speak of the operations, and he was under the impression that he had himself talked with the first patient upon whom an operation had been done. Between this certificate and the story as related to Sims, twenty-three years later, there seems to be an irreconcilable conflict.

"Up to the time of Dr. Long's death the relations between himself and Dr. Wilhite appear to have been very friendly. In his interview with Dr. Sims, in 1876, Wilhite said that 'Long was the real and original discoverer of anæsthesia, and believed he would be so acknowledged if all the facts in the case were fully set forth.' When Sims was in correspondence with both of them during the preparation of his paper, Wilhite wrote Long:

"ANDERSON, S. C., January 16, 1877.

"Dr. C. W. Long:

"DEAR DOCTOR: I have just received a letter from Dr. J. Marion Sims, of New York, stating that you will not write to him, or at least that he wrote to you about three weeks ago and had received no reply. If you don't do so soon it will be too late. He has been preparing an article for publication, and wants to place you right before the world. You have been apprised, I suppose, of the nature of the article. Why you have been connected with, and will be the leading spirit in, the article happened in this way: While I was in New York last summer at one of Dr. Sims's private operations, several prominent physicians being present, I happened to remark that I witnessed the first or second operation ever performed under an anæsthetic. Every one said that I was mistaken, and particularly Dr. Sims. . . . After that I met Sims at his office and gave him such particulars as I could recollect of your first operation, and also

* See *Transactions of the South Carolina Medical Association*, April, 1883, and also *History of Surgery in South Carolina*, by Dr. E. F. Parker, *North Carolina Medical Journal*, June, 1893.

urged your claims to the priority. He at once wrote you on the subject, and has since become very much interested in the matter.

"Now, doctor, it is but justice to you, as it is due the world, that you give Dr. Sims such information as he asks for at once, as he is going to all this trouble only to place the proper credit of this great discovery on the man who justly deserves it. I earnestly hope you will comply with the doctor's request as soon as possible. . . . As I have been the means of giving the investigation of this subject its present shape, I am exceedingly anxious that you should give all the information you can, that you may, and justly too, receive the credit of this great discovery. If you will act, it will certainly be so. Dr. Sims also wants a short history of your life, which don't fail to give.

"Hoping to hear from you, I remain yours, etc.,

"P. A. WILHITE."

"In reply to this, Long reminded Wilhite that he did not witness the operations, as stated, and asked him to send Sims a certificate similar in character to the one above quoted. Dr. Wilhite replied:

"ANDERSON, S. C., January 27, 1877.

"Dr. C. W. Long:

"DEAR DOCTOR: Yours of the 22d is at hand, and I have also just received a letter from Dr. Sims, which I will answer to-day. In regard to the certificate you spoke about, it will not be necessary, I think, as Dr. Sims has my statement written out in full. He was very particular to get all the points and facts I could recollect. In my statement *I did make a mistake about my being present at the first or second operation, which mistake I will correct.* (Italics mine—L. B. G.)

"If you still think proper, I will send a certificate. Let me know and I will give you any assistance in this great matter.

Yours truly,

"P. A. WILHITE."

"Sims's article appeared in May, 1877, and Long at once noticed the errors and the absence of the promised corrections. He requested Sims to correct the mistakes, but the latter replied that the 'misplacement of a few names and dates would not alter the main facts in the case.' He sailed for Europe in a few days, and the matter was dropped.

"The above is sufficient to show, beyond the shadow of a doubt, that Dr. Long was the 'real and original' discoverer of the anæsthetic properties of ether, and that he could not have received any assistance or suggestions whatever from young Wilhite.

"It is not material to the strength of Dr. Long's case whether the negro boy incident ever happened or not. However, there is no evidence to show that he knew anything of it until nearly forty years after it is said to have occurred. I have lately had an interview with Miss Fannie Long, to whom Dr. Long had often told and retold the circumstances relating to his discovery. In his later years she became thoroughly familiar with every detail of her father's claim, and at his death he confided to her keeping all the documentary evidence in his case. She tells me that the above story was related to Dr. Long by Dr. Wilhite himself, in the presence of several of the family, when Wilhite was on a visit to her father's house in the spring of 1877. After hearing it, Dr. Long replied: 'Doctor, this is the first time I ever heard of it.'

"There is living near this city an old gentleman, who still preserves a clear recollection of the events of that period, and to him I am indebted for the following letter:

"EDGEWOOD, DE KALE COUNTY, GA., June 27, 1893.

"Dr. L. B. Grandy:

"DEAR DOCTOR: In response to your inquiries, I will state that I was intimately acquainted with Dr. C. W. Long, and was

frequently with him after he located in Jefferson, Ga., in the summer of 1840. He often administered the vapor of ether to us young men of the village for the exhilarating effect produced, and he told me that he became acquainted with this property of ether while a medical student in Philadelphia. Upon one occasion, in the fall of 1841, I think, he remarked to me that he thought ether could be used to prevent pain in surgical operations, and that he intended to make the trial at his earliest opportunity. I moved to Athens, January 20, 1842, and introduced the inhalation of ether among the young men in that place. Before this time the practice of thus taking ether was unknown in that section. At Dr. Long's request, I sent him some ether from Athens in the winter of 1842. Shortly afterward he came to Athens, and told me that he had operated successfully under the influence of the ether.

"These are the facts as I now remember them. Up to the time that I moved from Jefferson, Dr. Long did not have any students in his office. If ether had been employed in sport in the neighborhood of Athens previous to my introduction of it there, I never heard of it. In reaching the conclusion that ether might be used in surgery, I do not think Dr. Long received any outside assistance. In my opinion, the idea was original with him.

Yours very truly,

"R. H. GOODMAN."

"The circumstances which led to Dr. Long's first operation are thus described by himself, in a letter to Hon. D. L. Swain, LL. D., June 4, 1866: *

"In December, 1841, a company of young men were in my office, and requested me to prepare some nitrous-oxide gas for inhalation. I informed them that I did not have the necessary apparatus for making it, but that I had an article which would produce like exhilarating effects, and which I considered equally safe. They expressed a desire to inhale it, and it was administered that night to most of the company. They were so well pleased with the effects that it soon became fashionable to inhale the ether, and I noticed persons while under its influence receive injuries which were sufficient to produce pain, but on inquiring of them if they suffered any pain, they uniformly told me that they had not. I noticed one young man receive an injury of the ankle joint, which disabled him for several days, and he informed me that he did not feel the slightest pain until the effects of the ether had passed off. Observing these facts, I was led to believe that surgical operations might be performed without pain, and proposed to the gentleman on whom my first operation was done that if he would submit to the operation while etherized, I would charge nothing, or only a nominal fee, for operating."

"This operation was for the removal of a tumor from the neck of James M. Venable, March 30, 1842. A second tumor was removed from the same patient on June 6th following.† The last clause in the above letter will explain the following entry in Dr. Long's ledger:

"JAMES VENABLE.

"1842.

"Jan. 28th—Sulphuric ether.....	\$ 25
"March 30th—Ether and excising tumor...	2.00
"May 13th—Sulphuric ether.....	25
"June 6th—Excising tumor.....	2.00

* Dr. Swain was the uncle of Dr. Long's wife, and at the time of this letter was president of the University of North Carolina.

† These operations were done in the presence of James E. Hayes, A. T. Thurmond, W. H. Thurmond, E. S. Rawls, afterward a practicing physician, and perhaps others. Certificates of these gentlemen are before me, besides also those of Venable's family.—L. B. G.

"The details of that first operation under ether have been published by both Dr. Long and Dr. Sims. Concerning the subsequent operations not much need be said.

"On July 3, 1842, Dr. Long amputated the toe of a negro boy for disease.

"On September 9, 1843, he extirpated a tumor from the head of Mary Vincent, of Jackson, Ga.

"On January 8, 1845, he amputated two fingers of a negro boy. The certificates of two witnesses to this operation state that the first finger was removed under the anæsthetic, and that the boy experienced no pain; that the second was removed without ether and was very painful. It occurs to me that Dr. Long's conduct in this case proceeded either from the fear of keeping the patient under the anæsthetic too long, or from a desire to test the action of the ether. The latter view is made plausible from a statement of Long lower down.

"If Dr. Long had promptly made public the results of his work, American medicine would have been spared the most tragically interesting chapter in its history. But, under the circumstances, he pursued a course both natural and commendable, and his reasons, as given by himself, were entirely cogent. He knew that he was the first to make the discovery, and he anticipated no controversy. His operations had all been of a minor character, and he only waited for an opportunity to test his anæsthetic in capital surgery. But cases of heroic surgery were not common in those days in the practice of a young physician, in a thinly settled community, one hundred and thirty miles from the nearest railroad. As far as it went, his work was well known in the small sphere in which he moved. Before me are several certificates—three of them from physicians who were prominent in that section at that time—to the effect that 'Dr. Long's operations were public and notorious in and near Jefferson, Jackson County, in the year 1842'; that he 'made no attempt to conceal the character of the article inhaled, nor made any request that the results of his operations be kept secret.'

"Dr. Long's delay in going into print with his cases is thus explained by himself:*

"I was anxious, before making my publication, to try etherization in a sufficient number of cases to fully satisfy my mind that anesthesia was produced by the ether, and was not the effect of the imagination, or owing to any peculiar insusceptibility to pain in the persons experimented on. At the time I was experimenting with ether there were physicians high in authority and of justly distinguished character who were the advocates of mesmerism, and recommended the induction of the mesmeric state as adequate to prevent pain in surgical operations.† Notwithstanding thus sanctioned, I was an unbeliever in the science, and of the opinion that if the mesmeric state could be produced at all it was only in those of "strong imaginations and weak minds," and was to be ascribed solely to the workings of the patient's imagination. Entertaining this opinion, I was the more particular in my experiments in etherization.'

"In the meantime Wells and Jackson and Morton were at work. With some assistance from one another they arrived successively at the anæsthetic properties of nitrous-oxide gas and sulphuric ether; and Morton . . . secured a patent on ether

under the name of *Lætheon*. In the Massachusetts General Hospital, Boston, October 16, 1846, Morton administered his 'lætheon' to a patient for Dr. J. C. Warren, and a tumor of the neck was successfully removed. Other operations followed in quick succession by the hospital staff. They were described in the *Boston Medical and Surgical Journal*, November, 1846, by Dr. Henry J. Bigelow. October 27, 1846, Jackson and Morton published their letters patent, announcing the discovery of 'lætheon' as an anæsthetic; but their 'lætheon' was nothing more nor less than sulphuric ether.

"Now began the celebrated 'Ether Controversy,' which I will pass over rapidly. Wells claimed the honor for himself, but having failed, both at home and abroad, to receive the recognition he sought, he ended his life by suicide January 14, 1848.

"When Dr. Long saw that he was anticipated in the matter of publication, he began at once to collect the evidence in proof of his own work. He obtained the affidavits of those operated upon, with dates, the sworn statements of witnesses and of those who knew of the operations, and his first article appeared, with some of these certificates, in the *Southern Medical and Surgical Journal* (Augusta, Ga.), December, 1849.

"In 1852 a bill was introduced in Congress to purchase Morton's patent for \$100,000. This was opposed by Dr. Charles T. Jackson and the friends of Wells. Dr. Long's claims were also presented, and Sims says they were formidable enough to block the movements of Morton to get the appropriation. In 1854 Jackson made a visit to Long in Athens, and, having satisfied himself as to the latter's priority in the use of ether, proposed to him (Long) to lay their claims conjointly before Congress as the real discoverers of anesthesia. At the interview between them Judge Andrews, of Madison, Ga., was present by Dr. Long's request. Dr. Long declined all of Jackson's suggestions, and instructed Senator Dawson, of Georgia, to make no compromise, but to place his claims solely on their merits. The matter drifted along with true congressional slowness until it was finally lost in the preparations for war."

The Hygiene and Advantage of Illness.—The following article appeared in the *Hospital* for September 23d:

"Sickness has been treated under many aspects, and it possesses an interest all its own. We propose to deal with it from the hygienic and moral standpoint. It is natural for the hale man or woman to regard illness with horror. Many fortunate people live so many years without ever being really ill that their sympathies with suffering become deadened, and may even cease to exist. We well remember an experience of this kind, which will come home, no doubt, to some readers. For many years it was our lot to spend the greater portion of each day in a hospital, surrounded by disease and suffering of all kinds. Providence mercifully ordains that those who have to be constantly with sick people grow to regard them from the point of view of how best to promote their comfort and recovery. This becomes an absorbing interest, and so the habitual attendant gradually loses all feeling of repulsion and dread. A casual visitor to a hospital ward is appalled by the evidences of suffering and sickness which surround him. Cases are recorded, and have indeed happened within our experience, where visitors can not bring themselves to remain in a ward, and have perforce to leave it, or they suffer from collapse. It must not, however, be supposed that the casual visitor has necessarily more sympathy with suffering than the habitual attendant. Indeed, it may be quite the contrary, the two effects being accounted for by the fact that the attendant is under self-discipline, while the visitor is not.

* Extract from an unpublished (?) paper read before the Medical Society of Georgia, April, 1853.

† Dr. Long here refers probably to Dr. Gibbs, of South Carolina, who at that time was especially prominent among the class of physicians above alluded to. He and others claimed to have "witnessed operations on patients mesmerized, and declared that mesmerism was the *ne plus ultra* needed to kill pain in surgical operations."—L. B. G.

"In our own case this discipline and the volume of work which had to be regularly mastered in the hospital pushed the sufferings of the patients into the background. We were unaware of the fact at the time, but a severe attack of illness forced it upon our attention. As we lay in the hospital suffering and helpless we began to realize something of the measure of the misery of the many thousands who had found it a house of recovery. This led to a keener appreciation of the privileges of being permitted to minister to the needs of helpless and suffering humanity. Our own illness thus became an education in itself, and led to results so beneficial as to fill the heart with gratitude and joy. Here then is one aspect of illness which all should strive to realize and profit by. Martial has truly said that life is not to live but to be well. We are, however, convinced that there is, after all, a privilege in being ill, which the most hale and robust may well envy the sick. Experience is a hard master, but his lessons possess a value more than commensurate with the pains he inflicts. Thus illness may make a hard man tender, a violent man patient, and a selfish man considerate for the feelings of others, for the rest of his life.

"We have thus far dealt with some of the moral aspects of sickness. What then of its hygiene? It may be argued that illness can not be hygienic; is this so? Who is there that has watched a splendid yacht traveling at great speed under full sail, and noted the moment when the squall struck it with such violence that it lay crippled on the face of the waters, and has not felt a pang of poignant grief? In the same way a man or woman may have been pointed out as the embodiment of splendid health, and in all respects a magnificent type of humanity. Suddenly an accident happens, and in a moment, like the yacht, the perfect human creature falls crippled and helpless. In such an instance we have a case where the hygiene of illness may be studied with advantage. The shock of the accident is keenly felt, and often as keenly resented. The life of the patient may hang in the balance, the injuries may prove permanent in character, and yet the victim may benefit much. The enforced idleness, the endurance of suffering, the restraints of sickness, and the prolonged rest, may build up and restore parts of the organism which were becoming overstrained, and so extend life and promote powers of useful work. In this way the hygienic influence of illness becomes a reality, and its value can not be questioned.

"The devil was sick, the devil a monk would be; the devil got well, the devil a monk was he.' So, too, hale people who have never known a day's illness in their lives, often consider good health as an added virtue in their own case. The less fortunate who suffer from illness are regarded as foolish or stupid, or at least as in some way lacking virtue. Good health may breed intolerance, inconsiderateness, or a selfish self-glorification. Now, it is a good thing to be healthy, but illness may bring blessings in its train. To be really ill is to produce thoughtfulness in the most ordinary of mortals. With thought comes a fairer sense of the proportion which health bears to individual merit. It teaches the value of kindness and skillful nursing, the power of ministering to others, the curse of selfishness, and the joy of doing something to leave the world a little better than we found it. There is then the mental and moral hygiene of illness which can do more to prevent the suicidal glorification of selfish souls than ordinary hygiene can do for people's bodies. Let us, therefore, give illness its due place. It may prove in its course unpleasant, painful, interfering, and hard to put up with, but against all this illness, when accepted in the proper spirit, can not fail to water barren soil, to destroy the spirit of self, to open the eyes to a higher and nobler philosophy, and to cut the patient off forever from paths which

lead to destruction. So illness rightly understood should, in most if not in every instance, prove a cause for thankfulness. There is also the joy of illness. Who that has ever been a convalescent—that is to say, a patient who, after much suffering, has reached the stage where disease has ceased and health has to be restored—and will not heartily admit the joys of illness? What more happy state can life provide than one where the invalid becomes conscious once more of the beauties of Nature, of the flowers, the sunshine, the fresh air, and the busy hum of life? Each day as strength increases and illness retreats into the background we become more and more joyous. Friends are once more beside us, books can again charm, every day brings more and more pleasures of life within our reach, and so promotes a feeling of joy altogether innocent, and yet the completest of all the joys we have ever experienced.

"There is a further joy, too! We can see as we write a dear friend, long since dead, who was brought by illness out of the darkness and misery of absolute worldliness into the glorious fullness of the joy of heaven. For months the dire suffering and agony of that illness were resented with bitter repining, but gradually the good seed took root, and the latter weeks were marked by a joyous recognition of the blessings which God in his mercy had brought to the sufferer through the dark shadows of a terrible illness. Yes, illness may prove a fruitful source of joy. The man or woman who leaves selfishness behind, when recovery takes place, the thoughtless person who re-enters the world of health as a man with a mind, and the poor sufferer who dies happy because a merciful Providence has conducted him out of the world along the pathway of sickness, are all proofs of the benefits which illness may bring in its train. We hope that what we have written, incomplete or imperfect though it be, may bring comfort and conviction to some minds, at any rate, who have heretofore been taught to regard illness as an unmixed evil, instead of a blessing in disguise."

The Diagnosis between Roetheln and Scarlet Fever.—

Attention has lately been called to the great good that would be likely to result from teaching the diagnosis of the acute infectious diseases clinically in special hospitals. In the *Lancet* for September 23d Dr. F. P. Atkinson says:

"The correct diagnosis between roetheln and scarlet fever is often a matter of very great importance and it is also one of extreme difficulty. When one refers to the various authorities on the subject the most conflicting opinions are to be met with. One says that the rash is like scarlet fever, another that it is like measles; one that it comes out with the fever, another that it appears two or three days after its commencement; one that it is ushered in with coryza, another that there is no coryza; and one that there is little or no desquamation, another that there is extensive peeling even of the hands and feet. With such diversity of opinion, how can the medical practitioner be expected to arrive at a correct diagnosis of these cases? One thing, I think, is certain, and that is that one must not rely either on the appearance of the rash or on desquamation; but there are two symptoms, nevertheless, which are well marked in nearly every case—viz., the initial fever is very short and the glandulæ concatenatæ are distinctly enlarged. It is more easy, of course, to detect the real nature of an epidemic when it occurs among a number of persons who are associated together in one dwelling than when they are scattered about in various localities, though at first, perhaps, even here the diagnosis may be somewhat doubtful. On June 7th of the present year I was called to see a boy aged twelve years at school, who had a somewhat dark, scarlatinal-looking rash on the neck and chest, a slightly ulcerated throat, and enlargement of the glan-

dulæ concatenatæ. The temperature was a little over 100° F. On the third day he was perfectly well in every respect, consequently the case appeared to me to be one of röteln. By way of precaution, he was ordered to be kept in quarantine for two weeks, to have an antiseptic bath at the end of that time, and to be dressed in perfectly fresh clothes before being allowed to mix with the other boys. Unfortunately, one important direction was omitted—viz., that he should be properly inspected at the end of the isolation period, and this, I hope, I shall not forget should another like occasion arise. On June 14th—i. e., seven days after the appearance of the first case—another boy sickened, but as he appeared to be only slightly ill the schoolmistress did not think it to be necessary to call in any medical man, but kept him isolated in the same way and for the same time as had been done in the first case. On July 2d one of the day scholars was attacked and in consequence was kept at home. The two medical men (partners) who saw him were for some time in doubt as to the nature of the illness, but subsequently they notified it as scarlet fever. The medical officer of health upon receiving this notification, and having heard that some of the other boys in the school had rashes, inspected all the remaining scholars on July 7th, and he found that the two boys who had been first attacked were peeling about the hands and that there were two others with a rash upon the neck, chest, and arms. All of these cases he considered to be scarlet fever, and immediately wrote to the parents of the boys (both boarders and day scholars) advising them to remove their children within twenty-four hours and offering to see to the disinfection of the clothing if they so desired. In addition to this, he called attention, as it were, to what was in the first instance, according to his opinion, an error in diagnosis, and thus, thoughtlessly no doubt, ran a risk of imperiling the friendship which generally exists between members of the medical profession. His suggestion of stopping the attendance of the day scholars was a sound one, as the homes of these boys were not likely to be subject to greater risks than they were before; but as regards the boarders it appeared to me that the case was different, as it was impossible to know how many more might at the time be infected, and if after removal other cases should arise, fresh foci would be developed and the disease might under certain circumstances assume much larger proportions. Had the house been sanitarily imperfect, and had fresh cases been breaking out daily, it might have been necessary to remove the pupils at once. On July 9th another boy fell ill, and also one on the 19th, one on the 21st, two on the 22d, and one on the 28th. I distinctly declined to notify the last three as suffering from scarlet fever, and I gave my reasons for so doing. Of twenty-two boarders, ten were attacked, and of the nine day scholars only one suffered. None of the mistresses, masters, and servants—eleven in number—were affected. In every one of the boys the rash showed itself on the first day of the illness about the neck and chest. In one case a second measly-looking rash appeared on the second day of the illness on the back. There was no distinct coryza in any single instance, but in two cases the eyes were suffused and watery. The tongue in all the cases appeared to be normal. The first boy who was attacked had a slightly ulcerated sore throat, but the others only complained of a little roughness and irritation. The lymphatic glands of the neck were in each instance more or less enlarged and remained so even after convalescence was established. The submaxillary glands were in no instance affected. In no case was the temperature above the normal on the fourth day; in two, however (the result probably of the very swollen and tender condition of one of the lymphatic glands), it rose again—in one on the fifth day and in the other on the eighth day; but permanently assumed the normal in

about a week—as soon, in fact, as the bowels, which had been previously constipated, became freely relieved. In one case there was no rise of temperature at all, and as a specimen of what it was in the others I will give three examples as follows: 1. July 19th—evening, 99.8° F. 20th—morning, 98.8°; evening, 98.8°. 21st—morning, 98.4°; evening, 98.4°. 2. July 22d—evening, 100°. 23d—morning, 98.6°; evening, 100°. 24th—morning, 98.4°; evening, 98.8°. 25th—morning, 98.4°; evening, 98.4°. 3. July 22d—evening, 99°. 23d—morning, 98°; evening, 98.6°. 24th—morning, 98.2°; evening, 98.6°. 25th—morning, 98.4°; evening, 98.4°. In no single instance was there any kidney complication, though the first boy bathed twice and the second once in the Thames while they were peeling. The extent and character of the desquamation varied greatly. In two cases the skin came off in large flakes from the abdomen, while there was slight scaling on the neck, hands, and feet. In another case there was only slight scurfiness, and this was to be seen about the groins, knees, and hands only. In yet another case there was slight peeling on the soles of the feet first, and on the neck, chest, and hands afterward. Most of the others had slight peeling of the hands and feet, but scarcely any of the body. The great difficulty in the early part of the illness was to keep the boys in bed and satisfy them with food. On July 22d I called in one of the medical men who had attended the only day scholar attacked to see the two boys who had sickened on that day, and after examining these and the convalescents he said that he felt inclined to alter the opinion he had previously formed.

"As regards the diagnosis of cases of this character, I think that besides the early subsidence of the initial fever and the enlargement of the glandulæ concatenatæ, the periods of incubation and infectivity will give some assistance. The report of the Clinical Society on this subject says, with regard to röteln, that the twelfth to the eighteenth day after the cessation of exposure is the time at which the rash is most likely to appear in epidemics in schools when a patient is isolated as soon as the rash appears. In a few cases the incubation period is only eight or nine days, and in a small number it may be only five or six days. The quarantine period must not be less than twenty-three days. As regards infectivity, the patient is infectious two or three days before the rash appears and while it is out; but it diminishes rapidly and altogether ceases in a week in mild cases, and in the more severe when desquamation is over. In the former class isolation for a week, to be followed by a bath and disinfection of clothes, is recommended, while in the latter it is advisable for isolation to be continued for two weeks, to be followed by disinfection, in order to prevent the spread of the disease in schools. The infection does not appear to be long retained by clothes. With respect to scarlet fever, the report remarks that the incubation period lasts usually between twenty-four and seventy-two hours; occasionally it is less than twenty-four hours. It is very doubtful whether it ever extends to eight days. When infection is conveyed by milk the period would seem to be two days or less. The infection period lasts from the onset of the symptoms until desquamation is complete and may still exist for eight weeks after the commencement of the disease. It is readily preserved and conveyed by fomites. A person who has been exposed to the infection of scarlet fever may, after disinfection of the clothes and other fomites, be pronounced to be safe if at the end of seven days he is free from fever and sore throat. It has been suggested that every medical man should study infectious diseases at the fever hospitals: but such cases as röteln, being so short in duration, would be rarely seen, and it seems to me that here the necessity of some sort of apprenticeship system clearly shows itself."

Original Communications.

TYPES OF GASTRO-INTESTINAL DISEASE PREVALENT IN NEW YORK.*

By FLOYD M. CRANDALL, M. D.

No region or country is exempt from the gastro-intestinal diseases of young children. In rural districts, where breast feeding is the rule, or where artificial food is obtained fresh and pure, they are at a minimum. In the crowded centers of population where the people are herded together in most unhygienic surroundings; where weak and puny children are born by the thousand in homes of poverty and vice; where artificial feeding is common; where milk is contaminated and many hours old when first received, they reach their maximum. In New York over thirty thousand young children have died of diarrhæal diseases during the last decade. From June to October the dispensaries are crowded with these little patients. The physician who practices among the well-to-do sees less of these disorders, for his families flee from the city and its dangers during the hot weather. But no general practitioner who remains in town escapes them entirely.

It is not my purpose to discuss the aetiology of the gastro-intestinal diseases, but rather to study their prevailing types as they present themselves in New York. The character and type of diarrhœa is modified by three factors—climate or season, social conditions, and food. It is not now the common belief that heat *per se* causes diarrhœa. That it is a powerful factor indirectly is undoubted, for it lowers the vitality of the patient, and favors fermentative changes in milk and the growth of pathogenic germs. Digestive disorders occur during every month of the year, but they do not become prevalent or very serious until June. There is occasionally considerable hot weather in May, but diarrhœa does not prevail to a serious degree. It frequently happens that no case appears in the large dispensaries before the 10th of June. The first case seen at the Polyclinic developed one season on June 10th, the next season on June 7th, while this year the first case did not appear until June 19th. Serious development of the disease does not as a rule occur before June 20th. It is most prevalent during the first ten days of July, the numbers being but slightly diminished during the next ten days. After July 20th the number of new cases decidedly diminishes. During the six weeks between July 20th and September 1st the development of new cases is remarkably uniform, being less than half that of early July, although the difference of the average temperature of these periods is but one or two degrees. During the first half of September the number of new cases is remarkably diminished, but during the latter half of the month there is a decided increase. The accompanying chart shows the date of onset of diarrhœa from June to November.

It would be an error to conclude that these variations were due to heat alone. Observations have abundantly proved that when the mean temperature has reached a certain point (about 60° F.) an increase of temperature is not

of necessity followed by an increase of the gastro-intestinal diseases. Numerous factors contribute to the results shown by the chart. One of the most important, it seems to me, is the fact that large numbers of feeble, marasmic babies are ready to succumb as soon as the hot weather produces the conditions favorable to the development of diarrhœa. It is simply the working of the law of natural selection. The unfit are the first to perish. It must not be supposed that the chart shows the actual number of patients under treatment at any one time. Many children who sicken in July continue ill in August. The actual number of children under treatment in August is greater than would be indicated by the chart.

The chart is especially interesting in our present study as it maps out very clearly marked changes in the type of disease. During June and early July the prevailing types are those of acute dyspeptic diarrhœa. In grouping these cases I use Dr. Holt's classification in Keating's *Cyclopædia*. In recording the histories careful observations were made of the character of the stools and their exact number. Until July 20th, twenty or even more stools in twenty-four hours are common. After that date it is rare to find that number. Serous diarrhœa marked by numerous profuse, thin, watery passages is common in June and July. In August the prevailing disease is marked by thicker grumous stools much less frequent in number. Acute dyspeptic diarrhœa prevails in July, enterocolitis in August, but in August even dyspeptic diarrhœa shows less tendency to assume a serous type than it does in July.

Early in September diarrhœa markedly decreases, but later in the month there is a decided increase. There is now a third and very radical change in type. The prevailing disease is the so-called dysentery. I am well aware that the term dysentery is not, from a pathological standpoint, proper. The term dysenteric diarrhœa expresses, however, the type of the prevailing disease. The passages

* Read before the Section in Diseases of Children of the First Pan-American Medical Congress.

are very frequent and small. They consist chiefly of thick mucus and blood and are accompanied by true tenesmus, high fever being present as a rule. These cases are frequently found grouped in certain tenement houses or in certain streets, and are apparently due to some contagious influences. A chart for 1889 would show the September rise far more marked than the one before you. Observation during the past four summers confirms the view, which I expressed in a paper read in 1890, that there are three quite distinct periods. The first begins about the middle of June and terminates about the middle of July, in which diarrhœa is more prevalent than at any other time, the serous type being common. The second extends from the last of July to the middle of September, during which comparatively few cases develop. The number of cases under treatment, however, is large, for entero-colitis is common, dating back in many instances to a dyspeptic diarrhœa in July. The third period occurs during the latter part of September, in which the cases are largely of a dysenteric type.

I have been unable to demonstrate that age has any material effect upon the type of disease. The statement that very young children are especially prone to serous diarrhœa has not been borne out. Of patients suffering from dysenteric diarrhœa, over eighty per cent. were under fourteen months. That form of disease seems prevalent chiefly among infants and children of ten or twelve years. As an ætiological factor, age is very important. I showed in the paper referred to that in three thousand cases occurring in New York 84·1 per cent. of the patients were under two years of age, and 53·2 per cent. were between six months and eighteen months.

The following observations were made upon five hundred and forty-one patients during the four years beginning with 1889. A history of disordered digestion preceding the diarrhœa—as slight diarrhœa, constipation, or indigestion—was obtained with certainty in forty-one per cent. of the dyspeptic cases. In a very large number of cases the previous condition could not be ascertained with certainty. Entero-colitis was almost invariably preceded by diarrhœa more or less continuous for a period ranging from a few days to several weeks. Well-defined entero-colitis developed with extreme rarity in perfectly healthy children.

The onset was sudden in seventy-two per cent. of the dyspeptic cases. It was frequently so definite that the mother could state the day and hour at which the first symptom appeared. In the remaining cases the onset was gradual or uncertain. In entero-colitis the exact date of onset or transition from dyspeptic diarrhœa could be determined in but twenty per cent. of the cases. The onset of well marked dysenteric diarrhœa was sudden and definite in over ninety per cent.

A curious fact was developed in this connection in studying the cases of two years. The interval between the onset of the diarrhœa and the first visit to the physician was found to be in June, 4·3 days; in July, 3·8 days; in August, 2·9 days. Hence, in August the child was brought for treatment almost a day and a half earlier than in June.

This is perhaps explained upon the ground that mothers did not appreciate the dangers of diarrhœa in June. In August, warned by personal experience or that of their friends, they seek medical aid earlier.

The number of passages per day was noted in four hundred and thirty-eight cases. In dyspeptic diarrhœa they varied from two or three per day to twenty, thirty, or more, the common range being from six to fifteen. In entero-colitis the extremes were about the same, but the usual number was more constant, ranging from eight to twelve. In dysenteric diarrhœa the extremes were from eight to forty, the average number being large—twelve to twenty. Within certain limits the number of passages is not a criterion of the seriousness of the disease. Some of the most serious and fatal cases which confront us are those in which the passages are large but not watery, of excessively offensive odor, and occur only at intervals of several hours. There may be but two or three in a day. They show a tendency to group themselves. An interval of five or six hours, or even longer, will pass with no passage. Then three or four will occur in quick succession, to be followed by another long interval without passages. The temperature in these cases ranges high and the constitutional disturbance is profound. The natural tendency is to terminate in death by toxemia. This type is not uncommon in New York. It illustrates very forcibly the fact that diarrhœa is, strictly speaking, a symptom, not a disease. Here we have excessive decomposition of the intestinal contents with grave constitutional disturbance, with very slight diarrhœa. The physician whose sole object in the treatment of these disorders is to check diarrhœa would lose cases of this character. The diarrhœa is a conservative process and is to be encouraged.

Allied to these cases are those in which the symptom of diarrhœa appears late. The child is fretful, restless, and apparently ill, with more or less fever. The condition continues for several hours—sometimes twelve hours or more—the bowels being constipated. When at last they do act, either naturally or as the result of a cathartic, the physician suddenly finds that he has a fully developed dyspeptic diarrhœa to deal with. The temperature is sometimes very high and the diagnosis is uncertain until large grumous, foul-smelling passages indicate the nature of the disease. The temperature usually falls when the bowels act, but, as a rule, unless active measures are taken, recovery does not occur.

Diarrhœa of the serous type is common early in the season, as we have already seen. It is not, however, true cholera infantum. It seems to me unwise to apply that term to ordinary summer diarrhœa. Cholera is a disease characterized by certain peculiar symptoms, and the term cholera infantum should be restricted to a well-marked but rather rare type of disease simulating cholera. I have seen in New York but five or six well-marked and typical cases of this class. In the western part of the State of New York it is somewhat more common than in the city. I would restrict the term to a disease which appears suddenly and is marked by frequent and profuse watery passages, which quickly drain the fluids from the body and reduce a

strong child in a few hours to a state of extreme danger. The temperature ranges high. Constitutional disturbance is profound. Prostration is alarming. The whole aspect of these cases, as I have seen them, is entirely different from that of ordinary dyspeptic diarrhœa, even when the stools are large and serous in character.

The color of the passages varied from the clear watery colorless stools of cholera infantum, and yellowish watery serous passages to yellow, green, brown, and black. Green, more or less decided, appeared at some period in seventy-one per cent. of all the cases.

Blood was present in the passages at some period in twenty-nine per cent. of the inflammatory cases not including the dysenteric, but was rarely profuse. It appeared in at least thirteen per cent. of two hundred and seventy-four dyspeptic cases, usually at the outset, and was several times profuse. The idea that blood is a symptom of inflammation, or of lesions, has no foundation in fact. In several instances the blood appeared in the first passage, but soon ceased, and the patient recovered without any symptoms of inflammation.

Vomiting was present in sixty-three per cent. of the dyspeptic cases. It usually occurred early and frequently disappeared after the first day or two, but was often persistent. It was more common in cases marked by watery passages and not infrequently preceded the diarrhœa. Vomiting appeared in forty-three per cent. of the inflammatory cases. It was not often persistent or continuous, nor as troublesome as in the preceding type.

Pain is a somewhat uncertain symptom in young children. In dyspeptic diarrhœa it was sometimes abdominal and gripping, but more commonly seemed to be of a bearing-down or straining character. There was frequently abdominal tenderness, but this was by no means a constant symptom. Pain was evidently present to a greater or less degree in most of the inflammatory cases. It was commonly of a bearing-down nature, and was sometimes a true tenesmus, accompanied not infrequently by a partial or complete prolapse of the rectum. Abdominal tenderness was, as a rule, present, usually in the umbilical or right iliac region, but distention or tension of the abdomen was not constant.

Temperature records in dispensary cases are necessarily imperfect. In seventy-two per cent. of the dyspeptic cases there was a history of fever or feverishness usually at the outset. Only twenty-one per cent. of the whole number of patients, however, showed a temperature of more than 100° at their first visit. It was frequently normal. In the septic type already described—marked by infrequent, offensive passages—the temperature, ranged high throughout, occasionally reaching 105° or 106° in fatal cases. Inflammatory diarrhœa was almost invariably marked by some elevation of temperature ranging usually from 99.5° to 103° . Except in cases of a dysenteric type, it was rarely very high. A slight, somewhat intermitting, but persistent temperature was the rule in entero-colitis.

From these studies we are able to present the following general description of the gastro-intestinal diseases common to young children in New York. The dyspeptic form

is commonly preceded by a disordered state of digestion. The onset may be gradual, but is usually definite and often sudden. Fever is generally present in the early stages, but thereafter is not constant. Two general forms are common, but are not sufficiently distinct to be classed as different varieties. One is characterized by watery, brownish, greenish, or light-colored passages occurring from ten to twenty or more times a day, accompanied frequently by vomiting, which is sometimes persistent. This is the so-called serous or choleraic diarrhœa. Classical cholera infantum is a rare disease. The other class, much more common, is characterized by semisolid passages, composed of fecal matter, white curdy masses or undigested food, mingled with serum, mucus, or blood, and of a variable color, but more often green. Fever, pain, and vomiting are frequent. The first form is rarely well defined, but usually originates from the second or merges into it, the same patient presenting at different times symptoms referable to each.

Enterocolitis, as a rule, develops gradually from a dyspeptic diarrhœa. The passages are usually green and frequently contain blood, mucus, and pus. Pain and abdominal tenderness are commonly present and not infrequently true tenesmus. Vomiting is common but not persistent. Fever to a slight degree is invariably present, but, being in some instances intermittent, single thermometric observations may fail to detect it. The course of the disease is extremely variable.

113 WEST NINETY-FIFTH STREET.

RECUMBENCY IN THE TREATMENT OF POTT'S DISEASE.*

By JOHN C. SCHAPPS, M. D.,

BROOKLYN, N. Y.,
ORTHOPEDIC SURGEON TO ST. MARY'S GENERAL HOSPITAL;
MEMBER OF THE AMERICAN ORTHOPEDIC ASSOCIATION.

THE collapse of a cavity resulting from disintegration of bone and fibrocartilage is not the only local element of the spinal deformity of Pott's disease. During the process of destruction the bone for some distance around that which breaks down becomes greatly softened. This change is not to be regarded as merely a part of the destructive process, but, as a great degree of protection against mechanical violence is thus afforded, it has a positive conservative value. The protection thus gained, however, is liable to be at the expense of change in shape of the softened bone itself, and it is this also, and not the bone destruction alone, which produces the deformity. In those cases which have no very acute symptoms, such as pain, night cries, marked spasm, fever, or impairment of general condition, but with a prolonged tendency to progressive deformity more rounded than angular, it is probably the predominating factor.

It has been shown that after removal of a tuberculous focus from the bones entering into the knee joint the sur-

* Read before the Section in Surgery of the First Pan-American Medical Congress.

rounding cancellous tissue remains for some months in a pliable state, so that without renewal of the osteitis it may bend and permit flexion of the limb; that this is corrigible by mechanical means, and that the bone ultimately becomes permanently hard.* The same conditions obtain in disease of the cancellous tissue of the spine, and after the destructive process has expended its energy the deformity may still be easily increased, but it is to a great extent controllable. Given a soft segment in the vertebral column, the kyphos is the mechanical result of weight and muscular action exerted in one or more of the following ways: First, as longitudinal pressure, by which the part is squeezed out; second, as anterior leverage, by which it is bent out; third, as direct backward pressure, such as intra-abdominal or intra-thoracic tension, or, in case of a patient supine upon a yielding surface, visceral weight, pushing out a weak portion of the parietes. It is of importance that these deforming forces be kept clearly in mind in order that counteracting force may be intelligently applied. Sudden, intermittent pressure, such as is produced by jars or twists, affects more particularly the destructive process, while long-continued pressure produces more effect in changing the shape of the surrounding bone. The same force may be destructive or passively deforming according as the active or passive condition of the parts predominates. Cicatricial contraction also plays an important rôle. Although conspicuous as a distorting factor in disease of joints other than spinal, its existence in this connection seems to have been generally ignored. An amount of cicatrization sufficient for the firm binding together of the parts adjacent to the bony defect is conservative, and it is fortunately improbable that any force which we can bring to bear can overcome it. But here, as elsewhere, inadequate protection in the acute stage may permit such a degree of disease intensity as will result in the formation of an unnecessarily large amount of scar tissue. This in contracting increases the deformity.

It is evident that inhibition of the destructive process is the most efficient preventive of the deformity, but as the latter is not necessarily proportionate to the former, and as the displacement of parts is traumatic in its effects, the deformity is treated not only for itself, but because it has a marked influence upon the causative destruction and upon the general health of the patient. In any stage of the disease the mechanical treatment consists in protection from traumatism, intrinsic and extrinsic, and antagonism of the deforming forces enumerated. But while no sharp distinction in kind is to be made between the therapeutics of the disease and that of the deformity, there is a very great difference between the degree of protection and of mechanical prophylaxis that is necessary for a spine in which progressive caries is in operation or very great softening exists, and that degree which will meet all the needs of one where, that process having ceased to operate, only a moderately weak place remains. Clinically, accurate determination is impossible and the treatment must be made

thorough enough for any possible state. The spondylitic spine when upright is unavoidably in performance of its functions as a support for weight and a base for muscular action. It is subject to a constant succession of traumatisms, accidental, those involved in the use of the limbs and thorax and those consequent upon misplaced muscular origins and insertions. The demand made by it upon any form of portative apparatus is therefore enormous. Such instruments have demonstrated a great degree of utility. Let us consider their limitations. Their action consists in support (principally antero-posterior) by leverage and in longitudinal traction. Unlike splints applied to a broken long bone or to a joint of a limb, where they act on long stiff levers, they have no direct grasp upon the seat of the disease nor upon the parts immediately adjacent thereto, but they include with the spine the moving thorax, the yielding abdomen with its heterogeneous and mobile contents, and to a limited degree the pelvis. And, in the acute stage, what force reaches the spine is expended not upon the bony defect or the seat of actual disintegration, but upon the soft mass surrounding it. This can not be pried straight while it is under the influence of pressure transmitted longitudinally through the spine. Antero-posterior support is also limited, in mid-dorsal disease, for instance, where the length of the spine above and below furnishes the best opportunity for leverage, by the amount of pressure which the skin over the kyphos will bear. In acute cases it frequently happens that this tolerance is not sufficient to permit a successful resistance to destructive and deforming force. As the back becomes sore the apparatus must be removed or modified to diminish pressure. This is but following up an increasing deformity, not successfully antagonizing it. In disease of the upper spine, where traction is the more essential element, similar limits are encountered. The immature pelvis of a child affords a poor base for traction. The skin covering the chin, back of the head, etc., will permit far less pressure than is involved in the weight of the head alone. Another indication of the inefficiency of portative apparatus is furnished by the convalescent spine. In the acute stage the area of reflex muscular spasm extends much beyond that of the disease. The extent of this rigidity is a pretty fair criterion of the intensity of the process. Frequently the whole spine is rigid, or may become so when the patient stands. In a case of dorsal disease a posterior brace fitted to a prone patient will either continue to fit when the patient stands or will cease to fit because he straightens his lumbar spine. But when the acuteness diminishes, the area of previous collateral rigidity becomes more flexible, and a brace now fitted to a prone patient does not follow the contour of the upright spine. The tendency of the healthy spine when vertical is to sag into curves, and the patient now lordoses away from the brace. Although some support had been afforded, it had not been sufficient to supplant reflex muscular spasm. It was the patient's muscles, to some extent at least, and not the brace, that had held him up. In some cases the patient has supported the brace more than the brace has supported the patient. These criticisms are applicable to any form of portative apparatus

* Deformity following Excision of the Knee. *Brooklyn Medical Journal*, February, 1892.

of whatever material constructed. Their use should be confined to the subacute or convalescent stage.

Recumbency as a therapeutic measure means mechanically more than simply putting a patient to bed. It implies protection from traumatism and retention of the whole spine in the best possible position, so that the relations of the separate parts remain unchanged or subject to those changes only which by the use of pressure and traction the surgeon may make. The prone posture is preferred by some surgeons, notably by E. Noble Smith, of London,* for the following reasons: 1. It removes the weight of the body from resting on the spine. 2. It restrains the action of the abdominal and other muscles in front of the spine so that the part of the body above the deformity is not bent forward. 3. It allows free use of the arms for feeding, play, etc., without causing the body to bend forward and press the diseased bones together. I have no experience with this posture, but, as compared with the supine, it would seem to be open, from a purely mechanical standpoint, to these objections: 1. It fails to afford the splintage which, in the supine position, the contact of the spine with the fixed surface of the couch affords. On the contrary, the anterior chest and abdominal walls being stationary, all the traumatisms of respiration and other thoracic or abdominal movements are effective on the vertebrae. 2. Deglutition, especially of liquids, and attention to the other needs of the body, must be much more difficult in the prone than in the supine position. 3. In cases where it is necessary to keep the head fixed in line with the trunk, the patient could not see what is going on, and confinement in this position would soon become very irksome. 4. Suppose the apex of the kyphos to be designated by a and a' , in the accompanying diagrams, the direction of gravity being indicated by the arrows. In the prone position (Fig. 1) such of the parts as underlie the kyphos are supported by the bed, and are themselves supporting the spine in its deformed position; there is nothing

FIG. 1.

to prevent the soft bone from being thrust out. In the supine position (Fig. 2) the trunk rests, in part at least,

FIG. 2.

upon a' , and the weight of the spine above and below the kyphos, together with that of the superincumbent parts, is reforming in its tendency.

That this last consideration is not a mere matter of theory, the accompanying tracings (Fig. 3), taken from an old case of dorsal disease, will very strikingly show. The first (a) was made by means of the lead strip applied to

the spine while the patient was prone. When cut out of cardboard, the edge fitted the spine accurately. The second

(b) was thus obtained: Several thicknesses of plaster-of-Paris bandage were applied to the mid-line of the back and closely secured by a muslin bandage. The patient was placed in the supine position upon a firmly padded table and kept quiet until the plaster had become hard. The muslin bandage was then cut away, and the patient lifted carefully out of the cast. By means of the lead applied to

a
FIG. 3.

FIG. 4.

the impression the contour of the cast was obtained, cut out of cardboard, and tested. These tracings have been placed together for comparison. While the general straightening of the spine is in part due to compensatory lordoses above and below the kyphos, even this change is a very desirable one; for, as emphasized by Whitman,* spinal deformity derives its importance chiefly from the resulting misplacement of the head, shoulders, chest, etc. The lordoses must, moreover, exert some straightening force upon the kyphos. The patient could by no means have tolerated, in the upright position, a brace that would have produced such a change. In a similar case were determined in both positions the transverse outlines of the projection. Fig. 4 shows the comparison. The upper is the profile in the supine, the lower in the prone position. The greater forward inclination of the ribs in the latter position is serious because it effects a projection forward of their sternal ends, and thus causes the characteristic pigeon breast.

The thorough support of the spine is not possible if the patient lies upon a soft or yielding material or upon a canvas-covered frame placed upon a bed from which it is raised several times daily; for the contour of the spine is not the same when the frame is suspended as when it is on the bed. Although no pain may be caused by thus changing the relations of the inflamed or softened vertebrae, such change tends to produce reflex spasm and is not surgical. The supporting surface should be quite firm, and the whole spine should be comfortably fitted. When the posterior projections of the occiput and the buttocks are greater than that of the kyphos, a pad tightly stuffed with curled hair, cork shavings, hair felt, or similar firm elastic material, should be placed under the latter. The hollows of the cervical and lumbar regions should also be filled in. On the other hand, care should be taken that the kyphos does not bury itself in the bed so that the

* *The Surgery of Deformities*. E. Noble Smith. London, 1882, p. 218.

* *Transactions of the American Orthopaedic Association*, vol. 9, 1892.

pressure above and below, or upon the ribs at either side, is greater than at the apex. The backward projection of the diseased area should be at all times directly antagonized by as much force as is practicable. It is essential that this force be subject to accurate adjustment without exciting reflex muscular spasm by interrupting the general condition of rest. This adjustment is not possible when the patient lies upon a board or other surface where no access is had to the spine. It is then due to slight deformity and good fortune if he does not have to be repeatedly taken up and the padding modified to meet the changing contour or to relieve some part of too concentrated pressure. Comfort is an essential criterion, and the same rule that applies to almost any kind of orthopaedic instrument holds good here. When it is a source of pain or discomfort it is not only not doing good, but is probably doing harm. Bathing (not rubbing) the parts with alcohol and water, equal parts, and the application of talcum, Fuller's earth, or a similar drying powder, are very necessary when sores form or are imminent. A very little turning of the patient will suffice for this purpose, but even this should, by a careful adjustment of the pressure, be avoided as much as possible, and should always be done by two persons—one at the head and shoulders, the other at the pelvis—working together so as to keep the relations of the parts unchanged. This is particularly necessary in cervical disease. In these cases the patient will not usually try to turn his head or lift it up.

Traction is particularly efficacious in cervical or high dorsal disease, and usually may be applied by means of a head sling similar to that employed in the Sayre suspension apparatus (Fig. 5). To the rings of this is attached a stout cord, which passes over a pulley and is fastened to a weight. It is well to have several of these slings made of drilling

FIG. 5.

FIG. 6.

and lined with Canton flannel, or made altogether of the latter, and with straps of webbing instead of leather. They can be washed when soiled, and are more comfortable. Fig. 6 shows a form of headpiece which is easily made, and answers very well in cases when a light weight is to be used and the occipital projection is well developed; it has the merit of not interfering with the lower jaw. It consists simply of a piece of webbing an inch wide, a buckle, and two inch-and-a-quarter iron harness rings. So long as the weight is pulling, the web has a good hold. After the ring has adjusted itself, the two layers of webbing are to be stitched together where they cross. I sometimes add a strap to pass from ring to ring under the chin. It can be removed, so that the patient may eat, without en-

tirely intermitting the traction. As compared with the other headpiece, this one has the disadvantage that the patient can slip it off when the nurse is not looking. When the case is acute, however, he is not likely to do so. The feet are placed from an inch and a half to four inches lower than the head, so that the greater mass of the trunk and lower extremities affords a good base for countertraction. The amount of weight is to be regulated by the patient's feelings. From half a pound to four pounds, in case of a young child, is sufficient to counteract muscular spasm and render him comfortable. In the middle and lower dorsal disease, traction is not so efficient. The patient should be nearly or quite horizontal, because the amount of pressure involved in drawing the upper segment of the trunk up hill is greater than the chin and scalp will long stand. In these cases, if attempt at much traction is made, the pelvis should be secured by adhesive plaster applied to both lower extremities, as for hip disease, or by the belt shown in Fig. 7. This is made of canvas or drilling, and padded where it lies on the crest of the pelvis. It is laced on and buckled to straps passing to the foot of the bed, and also to those around the side bar of the stretcher frame. But, as stated,

FIG. 7.

the undeveloped pelvis of a child offers a very poor hold for traction. The belt is of more service in securing the pelvis so that the patient can not turn over. While the amount of weight should be all that the patient can tolerate, it is evident that the leverage illustrated in Fig. 2 is a more powerful agent than traction in these most formidable cases. In lumbar disease the head should be placed a little lower than the feet. The pelvis is to be fixed as before, and the extending force consists of the head and thorax with as much additional weight as is comfortable. When psoas contraction exists, an adjustable inclined plane is used, with traction on the flexed limb.

At the annual meeting of the American Orthopaedic Association held in New York, in September, 1892, I presented an orthopaedic couch which seemed to be all that was necessary for its purpose. Further experience has demonstrated its inadequacy, and impelled me to make experiments in devising a bed which will more fully meet the requirements already outlined. The surgical cot which I now present comprises a modification of the familiar canvas-covered frame, with provision for supporting it and maintaining uninterrupted rest, fixation, and accurately adjusted pressure and traction. Fig. 8 shows it open; Fig. 9, closed. It consists of a rectangular frame of iron, a canvas bottom, and an iron support, upon which the frame is adjustable at any convenient height or incline. The rectangular frame must be stiff enough to stand, without bending, the patient's weight and the strain involved in stretching tightly a heavy canvas. It should be from four to six inches longer than the patient (forty-eight by fifteen inches inside will be found a convenient size for children under five years old), and it should

be made of three-eighths inch pipe. Larger sizes should be made heavier. The canvas should be No. 2 for sizes under forty-eight inches; thicker for larger sizes. It is to be hemmed and made a little shorter and narrower than the frame to allow for stretching, and provided with eyelets

canvas (Fig. 10). They should be about six inches wide, long enough to extend an inch or two above and below the projection, and be a half to three quarters of an inch thick, except at the ends, where they are flattened. They are placed longitudinally each side of the middle, so that a groove about a half to three quarters of an inch wide exists between them. Their object is to press upon each side of the prominent spines, and to protect the bony projection. The patient is replaced upon the canvas and the shoulders are secured by the straps. To exert a pressure upon the kyphos in such a way that it may be accurately regulated, there is the following arrangement: Two, three, or more straps of webbing are placed side by side transversely under the canvas and across the kyphos so as to buckle at each end around the iron frame. By the use of these straps, which constitute a most important feature of the apparatus, the reforming pressure is always under control, while the weight of the parts anatomically above and below is brought into play to secure a backward leverage. The cervical and lumbar hollows should

be filled by small pads without groove sewed on. The sagging of the canvas results in the formation of a shallow trough which interferes with lateral motion, and as the material yields to the warmth and pressure of the prominent parts after a few days, the back is generally accurately fitted. By feeling the under side of the canvas it may be ascer-

through which pass stout cords by which it is laced to the frame. Warming the canvas will assist in getting it tight. A hole, preferably a narrow oval, is provided for the purposes of micturition and defecation. It should measure, for a child under five years of age, six inches by three inches and a half. Its long diameter coincides with the longitudinal median line of the canvas, and the center should, when the spine has not been shortened, be about three fifths distant from the top. When the spine has been much shortened, a special canvas will have to be made. The edges of the opening must be strongly and neatly bound and hammered flat. The vessel is placed underneath, supported at the proper height by a stool, box, pile of books, or in some such manner. It is brought to the patient, and not the patient to the vessel. The opening is closed by an under flap a little broader than the hole is long. One end of it is sewed to the edge of the canvas, and the other secured by three or more stout straps arranged to buckle around the side of the frame.

The patient is laid upon the couch in the position he is to occupy, so that the anus is placed at the upper end of the opening. The locations of the neck and axillæ are marked upon the canvas, and marks are also made by means of which the situation of the kyphos can be determined. He is then removed. Padded straps of webbing, arranged to pass around the shoulders and through the axillæ and provided with buckles, are sewn to the canvas. The buckles should be placed close to the sides of the neck, where they will be least accessible to the patient, and the straps diverge. The sewing can best be done with a sailor's palm and needle. A strap to lie loosely across the chest and having in each end a loop through which the shoulder-strap passes will prevent the slipping off of the latter. If the case be one of cervical or high dorsal disease, loose pads of kersey, hair, felt, or some similar elastic material covered with linen can be easily placed under the neck. But for lower spondylitis the pads should be sewed to the

tained whether such is the case. The weight of the body serves to maintain a close contact with the couch. The lacing should be tightened from time to time. The most perfect fixation of the spine is secured by the application to the back of some rigid material; but this involves the danger of pressure sores, or, to prevent them, a frequent removal and reapplication of the apparatus. Thus the patient must be turned over frequently. In most if not in all cases sufficient fixation is attained by fastening the patient to the couch by means of the shoulder straps by webbing passed around the side bar and buckled to the pelvic belt and by the use of traction. A pillow should be put under the lower extremities to prevent pressure on the heels and also to relax the flexors. A towel fastened around the rectangular frame and the thighs prevents the patient's kicking. The covering is also wrapped around the patient and the frame and so keeps the back warm.

For the purpose of applying traction there is a broad, flanged, wooden pulley which turns on a steel bar placed

FIG. 8.

FIG. 9.

across either end of the apparatus at any convenient height. The cord connecting the head-sling and the weight is passed two or three times around this drum, and so can not be thrown off. Should the patient move his head laterally, as may be allowed in convalescent cases, the pulley and weight follow the movement. I have sometimes secured the headpiece to the top of the frame and allowed the weight of the parts below the disease to act as the tracting force. Steele, of St. Louis,* fastens the side rings of the headpiece to uprights placed at a considerable distance apart in the head of the frame which he employs, and thus secures some lateral fixation of the head. By the use of the cot I have been able to keep up an absolutely uninterrupted rest with traction, and render the patient perfectly comfortable for months at a time. The addition of rubber-tired wheels and a parasol has contributed to the comfort

saved from all traumatisms, except that of respiration, is thus placed in the best possible condition for repair; and what is of great importance, fever and the drain of muscular spasm, pain, and perverted nutrition are met by a state of systemic rest.

A feature about this measure in chronic bone disease which is surprising to all to whom it is not familiar is the way patients thrive under it. It is true that while a gain in weight is the rule, the muscles soon become soft, and a loss of muscular strength may occur. This loss is a gain; to the spondylitic spine muscular strength is a menace. So long as the nerve connections are preserved the muscle remains capable of restoration, and no permanent damage by rest is possible. Nature never makes the mistake of demanding as a condition of recovery the use of any parts (as in this case bones and muscles) which are unable to perform

their functions. When the fixation and traction are efficient, patients are relieved of pain, sleep well, and soon lose the drawn, old, tired expression so familiar upon the faces of those suffering from the great drain of prolonged muscular spasm. I believe that the amount of caries is thus materially limited, that much deformity is prevented, and that the duration of the disease is materially shortened. Another merit of this therapeutic measure is that its employment does not demand the exercise of the mechanical skill and experience which are necessary to the successful employment of a portative apparatus. In places where a spinal support can not be readily obtained, recumbency with regulated pressure and traction may be adopted until other arrangements can be made. Patients may, if necessary, be moved long distances, and with safety and comfort, upon a frame.

Recumbency is indicated as routine treatment as soon as the diagnosis of spondylitis has been made, or even when

FIG. 10.

of the patient and the convenience of the friends. The cot is made in sizes up to fifty-six inches by W. F. Ford, of New York.

It is evident that when the patient is recumbent all the indications may be more perfectly met than in any other position. The force of gravity, which by leverage and by longitudinal pressure acts upon the upright spine as a powerful destructive and deforming agent, can now be converted into a reforming force. Direct backward pressure can be accurately antagonized. Muscular action and interosseous pressure, now greatly reduced by the general condition of inactivity, can be counteracted by fixation and by far less traction than would be required to raise the weight of what were superincumbent parts. The spine, relieved of the performance of all its active functions and

it is probable; for the intrinsic tendency of the disease to progress is in each new case such an unknown quantity that no time should be expended during the developmental stage by experimenting with less thorough methods of treatment. In case of a patient wearing a support, progressive deformity or the persistence of pressure sores should be regarded as demanding recumbency. It is, of course, presumed that the brace had been skillfully designed and applied, that pressure had been diffused over as much surface as the case will permit, and that by cleanliness and dryness every care had been taken to protect the skin. While no method can claim to prevent in all cases an increase of deformity, such increase should in no case be regarded as inevitable until it is ascertained what can be done by the careful use of mechanical force applied to the passive horizontal spine. Marked psoas rigidity denotes a

* *Medical Fortnightly*, St. Louis, February 1, 1891.

considerable degree of activity of the disease, and probably abscess. When the patient walks or stands with the thigh flexed, the forward inclination of the trunk causes the weight of the mass above to act at a great mechanical advantage in the production of deformity. Support is thus made very difficult and uncertain, and femoral movement exerts, through the shortened muscle, a direct traumatism upon the diseased spine. These cases should be treated in the horizontal posture, and the limb elevated upon an inclined plane sufficiently to relax the psoas muscle. By means of adhesive plaster a weight is attached to the limb and traction made as in hip disease. As the muscle relaxes the plane is to be lowered. Pott's paralysis, even a slight dragging with exaggerated reflex, should be regarded as an unequivocal indication for recumbency with all possible traction. Many very brilliant results, even when there were present incontinence of urine and feces and large bedsores, have thus been obtained. Patients with abscess should generally be treated in the horizontal position; always if the abscess is new or increasing. Night cries, a grunting respiration, peripheral pain referable to the spinal nerves coming from the seat of the

ful whether the case is doing as well as it should may be regarded as an indication for recumbency.

I trust that this cot, aside from its employment in Pott's disease, may be found of service in any case, surgical or medical, when prolonged rest is necessary. It has proved very serviceable in rhachitic spinal curvature. For hip disease with flexion the inclined plane may be used, as in psoas contraction from spondylitis. In fracture of the femur the railroad splint may be employed. It should extend well up to the buttock and is a very perfect means of preventing eversion. The tops of the uprights, at what might be termed the head and the foot of the couch, may be joined by steel rods adjustable to any height, and across these may be placed longitudinally, like a ridge pole, a bar. This is located over the middle or at either side, and is intended to support by slings an arm or a leg (Fig. 11). It has been used to secure both lower limbs in a vertical position for fracture of the thigh. It is not recommended in spinal disease, as the patient may try to raise himself by it. This ridge pole and the uprights may be useful to hold up a mosquito net. A tray is easily added, or a light sewing table may be placed over the patient. I

Fig. 11.

disease, an inclination of the patient to lean on chairs, etc., indicate an insufficient support and the need of recumbency.

It is evident, however, that confinement to the cot can not be continued during the whole course of a spondylitis, nor is this necessary. When, by the absence of pain, fever, and progressive deformity and by a diminution of the area of spinal rigidity, we are led to conclude that the acute or actively destructive stage of the disease has passed, the patient may gradually be allowed more freedom under the protection of an apparatus carefully adapted to the needs of the case. This is *always* done tentatively with watchful supervision; and the slightest increase of deformity, or an occurrence of pain or irritability, or the evidence by face, attitude, or gait that he is not getting the proper support, should be the indication for a return to the horizontal position. This holds good at any time in the course of the disease, and any intercurrent change which makes it doubt-

ful whether the case is doing as well as it should may be regarded as an indication for recumbency. I think by the use of this couch, which does not occupy much more floor space than the patient, a helpless child or young person may be quite easily handled, and may be readily moved about the room, placed near the window, or taken out into the sunlight and fresh air. The little invalid's world would be thus greatly enlarged. When the opening in the canvas is not to be used, a water or air bed or any kind of mattress may be employed, or the canvas may be replaced by iron springs. When the cross-pieces and the ridge pole are taken off and the uprights folded down, the couch may be converted into a stretcher with or without wheels; or the rectangular iron frame alone may be so used. I hope

soon to present a bed of a construction better adapted to the needs of adult patients.

THE PROXIMATE CAUSE OF THE TRANSIENT FORM OF MYOPIA ASSOCIATED WITH IRITIS.

WITH REMARKS ON OTHER FORMS OF SYMPTOMATIC AMETROPIA.*

By A. SCHAPRINGER, M. D.

THE clinical fact that iritis in a considerable proportion of cases is apt to occasion a transitory myopia of low degree—about 1.5 D. to 2.0 D.—was first put on record by Dr. John Green, of St. Louis, the well-known authority on questions connected with refraction. Since the time that he

* Read before the Section in Ophthalmology and Otology of the New York Academy of Medicine, October 16, 1893.

read his paper on this subject before the American Ophthalmological Society in 1887 his discovery has been verified by a large number of other observers.

As to the proximate cause of the increase of refraction as a symptom of iritis Dr. Green did not offer any speculations.

In a paper on Symptomatic Myopia, read before the American Ophthalmological Society in 1888, Dr. W. F. Mittendorf advanced the theory that this transient increase of refraction was the result of an infiltration of the anterior portion of the vitreous body, increasing the bulk of this organ to such a degree as to push the lens system forward and with it the posterior principal focus of the eye. This theory I do not feel inclined to adopt, because as long as the tensile strength of the suspensory ligament of the lens remains unimpaired, an increase of pressure in the vitreous chamber would have to be very great indeed to displace the lens forward. The globe would feel very hard on palpation, other symptoms consequent upon increase of tension would be present, and there would be hardly any difference in the clinical pictures of iritis and acute glaucoma.

According to another theory, the increased refraction is said to be due to an augmentation in the corneal curvature produced by the increased pressure of the lids in consequence of the great photophobia. The negative results of ophthalmometric measurements completely disprove this theory.

Still another hypothesis alleges a spasmodic condition of the ciliary muscle as the cause of the symptom in question. This hypothetical cause forming the base of certain therapeutical recommendations lately made by Dr. Charles A. Oliver, of Philadelphia,* the question of the correctness of this hypothesis must henceforth be regarded as not merely of theoretical but also of practical interest.

Dr. Oliver insists that the refraction of the eye should be carefully and repeatedly tested in the course of an attack of iritis, and that instillation of strong mydriatic solutions should not be discontinued as long as the increased refraction persists, even after the pupil has been fully dilated. The presence of myopia proves the presence of spasm in the muscle of accommodation, and this being a pathological condition, it needs to be combated by the appropriate means at our disposal.

Now Dr. Green has already pointed out that the fact that the increase of refraction persists for an indefinite time after the pupil has fully yielded to the action of atropine was a proof militating against the assumption that the transient myopia was due to spasm of accommodation. Besides this argument advanced by Dr. Green, the supposition that inflammation will cause a spasmodic contraction of the ciliary muscle is contrary to all physiological experience in regard to analogous conditions elsewhere in the human organism. To bring forward only one example, let me refer to the behavior of the muscular coat of the intestine in peritonitis, where it is anything but contracted.

On the contrary, it is completely paralyzed, and by its paralysis causes two of the main symptoms of the disease, tympanites and constipation. The contraction of the pupil in iritis is not due to spasm of the sphincter iridis muscle, but is only dependent on the swelling of the tissue of the iris in consequence of hyperæmia and infiltration. It is also a very significant fact in connection with the question here discussed that in the insidious forms of sympathetic iridocyclitis the first sign of impending trouble is the *diminution* of the power of accommodation, causing recession of the near point.

Having dismissed all the theories hitherto enumerated as unsatisfactory, it behooves me to substitute one against which no valid objections could be raised. I think that the transient myopia of iritis can be best explained by a temporary increase of the refractive index of the aqueous humor. That the composition of the contents of the anterior chamber in iritis differs from that in the normal state is not a hypothesis, but a fact. The formed particles suspended in the aqueous humor, rendering its aspect turbid, will, of course, have no influence upon the refraction of the eye. We are here concerned only about the transparent part of the liquid. Judging from the deposits, among other substances, of fibrin upon the walls of the anterior chamber, nothing would seem more plausible than to assume that in iritis the aqueous humor contains this substance in more than the normal quantity. If this is the case, it follows from physical laws that its index of refraction must be increased. A higher index of refraction of the aqueous will produce myopia, because the beams of light which receive an inclination toward the optical axis, when refracted at the anterior corneal surface, will receive an additional inclination toward this axis at the posterior corneal surface. In the normal state there is no refraction at this surface, because then there is no difference between the refractive indices of the cornea and of the aqueous humor. The posterior wall of the cornea in iritis represents a convex refracting surface with a medium of higher refrangibility behind it than before. Consequently the optical conditions present at this surface will be the same in kind, though not in degree, as those present at the anterior surface.

If the refractive index of the aqueous humor of an emmetropic eye were lessened instead of increased, the inclination of the rays of light toward the optical axis would be diminished and the eye therefore rendered hypermetropic.

The question now presents itself, How much must the index of refraction of the aqueous be increased in order to produce a given degree of myopia?

In order to solve this problem, we have to take into consideration the factors coming into play at the refraction by the posterior corneal surface. The relation of the constants is expressed by the well-known formula—

$$F_2 = \frac{n_2 r}{n_2 - n_1}$$

We wish to calculate the value of n_2 , which represents the index of refraction of the aqueous humor:

$$n_2 = \frac{F_2 n_1}{F_2 - r}$$

* La correction exacte des vices de réfraction dans l'iritis plastique. *Annales d'oculistique*, Jan., 1893.

F_2 represents the second principal focal distance of our refractive system, consisting of corneal substance, posterior corneal surface, and iritic aqueous, or, in other words, the collective power of this system. This collective power is measured by the concave glass placed before the eye, neutralizing the collective power by its dispersive power. In substituting the reciprocal value of this glass, we have to deduct the distance of the correcting glass from the posterior corneal surface.

n_1 stands for the refractive index of the corneal substance, which is 1.3365 according to Helmholtz.

r represents the radius of curvature of the posterior wall of the cornea, which, following Tscherning, we will put down as six millimetres.

Carrying out the calculation for different degrees of myopia as met with in iritis, we find the following values of n_2 :

Degree of myopia.	Index of refraction of aqueous.
1.0 D	1.345
1.5 D	1.349
2.0 D	1.353

The increase from the normal—which is 1.336—not being considerable, the figures at least do not speak against the plausibility of our hypothesis.

If we accept this hypothesis as the true explanation of the myopia occasioned by iritis, we shall refrain from continuing the instillations of atropine after the pupil has fully yielded to its action and the congestion has subsided, although the myopia may still be present. Our theory furnishes a contraindication against the persistent employment of atropine under these circumstances, inasmuch as a dilated pupil means an obstructed iris angle, and this means interference with the drainage of the anterior chamber. We shall not feel inclined to do anything to keep the morbid aqueous humor longer in the anterior chamber than necessary. Our hypothesis furthermore does not impose upon us the obligation of carefully and repeatedly testing the refraction of eyes affected with iritis, of which release we shall avail ourselves with avidity and earn the thanks of our patients.

If the myopia persists for some time after the subsidence of the inflammatory symptoms and we should feel called upon to hasten the work of Nature, massage of the eyeball would offer itself as a local therapeutic measure in consonance with our theory.

The two recognized varieties of myopia in general are axial myopia, which is the most common form, and myopia of curvature. If our theory as to the causation of the transient nearsightedness occasioned by iritis is verified, we shall have "index myopia" as a third type of this error of refraction.

To test the merits of the theory here propounded, very accurate measurements with instruments of precision rarely met with in the possession of practitioners will be necessary. Those who have a Helmholtz ophthalmometer, or, what seems to be a still more suitable instrument for the purpose, a Tscherning ophthalmometer at their disposal, will deserve the thanks of the profession by taking up this problem. The shortest way to determine the re-

fractive index of iritic aqueous would be to tap the anterior chamber and test the liquid obtained by means of an Abbé refractometer; but the clinical indication for paracentesis of the cornea hardly ever arises in the course of plastic iritis.

Since we are discussing the subject of index ametropia, the question naturally suggests itself, What would become of an emmetropic eye if the index of refraction of the vitreous body be increased?

The answer to this question will be found in the following consideration:

The beams of light, striking the concave anterior surface of the vitreous, are deflected toward the optical axis to join it at the place of the retina. The strength of the deflection depends upon the difference of the refractive indices of the crystalline body and the vitreous. The index of the vitreous being the lesser quantity, we will, by increasing it, lessen the difference between it and the crystalline index, or, in other words, lessen the inclination of the rays of light toward the optical axis. This means that the emmetropic eye is being rendered hypermetropic.

A change in the refractive index of the vitreous will therefore have the opposite effect from that which is produced by the same kind of change in the aqueous.

In the intervals between the prodromic attacks preceding an outbreak of inflammatory glaucoma the patients usually complain of being compelled to use increasingly strong convex glasses in rapid succession for reading purposes. This is usually explained as the result of a rapid diminution in the power of accommodation, but it seems to me not improbable that this symptom may have something to do with an increase in the refractive index of the vitreous body. Such an increase, as said before, will render an emmetropic eye hypermetropic, and a hypermetropic eye still more hypermetropic. I have met nowhere with the distinct statement from any observer that, while the near point of the glaucomatous eye thus rapidly receded, the far point was found to remain stationary.

The myopia caused by diabetes is a form of myopia to which Hirschberg has called attention and which is probably also a type of index ametropia. I have myself recently met with two cases of this kind in succession—one of them in a lady sixty-one years old, referred to me by the kindness of Dr. S. J. Meltzer, of this city. The acquired myopia in both cases was of considerable degree, being more than 6 D. An increased curvature of the front surface of the lens I can hardly deem accountable for this, since the depth of the anterior chamber, at least as far as could be made out without the use of the instruments of precision mentioned before, seemed perfectly normal in both cases. A decrease in the refractive index of the cortical substance of the lens will, I think, best account for this type of myopia, if the myopia is to be accounted for by a change in this organ. Such a decrease will increase the refractive power of the lens system as a whole and thereby bring the posterior principal focus of the eye in front of the retina. It may sound paradoxical at first that the collecting power of a biconvex lens like the crystalline body should be increased by a decrease in the refractive index

of one of its constituent parts. But it must be remembered that the cortical substance represents a system of concave or dispersive lenses which neutralize the over-strong collective power of the globular nucleus. By lowering the refractive index of the cortex we lessen its dispersive power, and the result will be a preponderance of the collecting power of the nucleus; the principal focus of the eye is thereby brought forward and the eye made myopic.

Since writing the foregoing my attention has been drawn to a paper, On the Presence of Sugar within the Eye in Experimental Diabetes,* by the brothers Cavazzani, an abstract of which has recently appeared in the *Centralblatt für prakt. Augenheilkunde* (supplement for 1892, p. 496). Having made experimental researches on the functions of the pancreas, these authors report the results of the chemical analysis of the refracting media of two dogs which were afflicted with a permanent form of diabetes in consequence of the extirpation of the pancreas. The animals were killed in due season and their eyeballs enucleated. In the first dog the aqueous humor contained 0.386 per cent. of sugar. In the peripheric layers of the lens very little of this substance was found, and none at all in the nuclear portion of the lens and the vitreous body. In the second dog sugar in the proportion of somewhat less than 0.05 per cent. was found in the aqueous humor and none at all in the other refracting media.† The lenses were completely transparent and anatomically normal in every respect. The fact that the lens, at least of one of the animals, contained sugar, speaks against the theory enunciated by Deutschmann,‡ which says that no sugar can diffuse into the substance of the lens as long as the epithelial layer of the lens capsule remains intact.

In the investigations of the Italian experimenters, at least as far as they are reported in the *Centralblatt*, no attention was paid to the refraction of the eyes during life or to the refractive index of the media subjected to chemical examination. I hope that in future investigations of the same kind these matters will not be lost sight of. The results of the chemical analysis make it probable that the aqueous humor at all events plays an important part in the production of diabetic myopia. Future investigations will have to show whether the peripheric layers of the lens are also concerned in this change of refraction and how far. It is very characteristic that the vitreous body of the diabetic dogs was found absolutely free from sugar. This is in remarkable harmony with what was pointed out before on theoretical grounds—viz., that the degree of myopia produced by an increase of the refractive index of the aqueous humor will not become further increased by an increase of the refractive index of the vitreous body, but, on the contrary, an increase of the refractive index of the vitreous would neutralize, more or less, any myopia caused by a change of index of the aqueous humor.

* This is a portion of a larger work, *Le funzioni del pancreas ed i loro rapporti colla patogenesi del diabete*. Venezia, 1892.

† From the marked difference in the chemical behavior of the aqueous and the vitreous the authors draw the conclusion that the sources of nutrition of these two substances must be entirely distinct.

‡ V. Graefe's *Arch. f. Ophthalm.*, 1887, p. 229.

ONE HUNDRED OPERATIONS FOR SEVERE STRUCTURAL DISEASE OF THE ABDOMINAL AND PELVIC ORGANS OF WOMEN.*

By I. S. STONE, M. D.,
WASHINGTON, D. C.

THE author has adopted the usual method of surgeons in reporting cases as they occur in practice. It is also convenient, as it furnishes one an opportunity to take into consideration the propriety of methods and an inventory of results. The present list includes my work in this department from November, 1888, until the end of February, 1893. By far the greater part of this surgery has been done in Columbia Hospital in this city, where excellent facilities are afforded.

It is the rule in this hospital to call a consultation of the staff to determine if the case in question be a suitable one for operation. It is not my purpose to consider here the advisability of this rule, but one very excellent purpose is accomplished by it—i. e., the prevention of unnecessary surgery. There can be only slight danger of a charge of too frequent use of the knife or of undertaking too many easy operations, although there is danger of disadvantage to the patient from delay. On the other hand, it is the custom to operate only when life is in danger, or when the patient is no longer able to work, and when definite and generally extensive disease can be discovered by any one not necessarily an expert in pelvic examination.

The list shows how large a proportion of cases of pelvic abscess, or tubo-ovarian abscess, have been treated. On the other hand, it may be seen how rarely have operations been performed for "oophoritis," salpingitis, etc. Again, it may be observed how seldom operation has been done early enough to find only "pyosalpinx." In but six cases in forty-four, where pus was present, could it be said that the disease had not extended beyond the tube. These were not necessarily recent cases, for they were in some instances still "pyosalpinx" after years of waiting and suffering, and good, bad, and indifferent treatment. The rule is nearly correct, however: first elytritis or endometritis, then salpingitis, pyosalpinx, tubo-ovarian abscess, and pelvic abscess. The period of time required to accomplish these steps in the formation of a pelvic abscess differs greatly, and bears intimate relation to the cause of infection. Of this I shall not write at present.

Pelvic Abscess.—Seventeen cases of pelvic abscess were treated by radical operation, with five deaths. Of the seventeen, seven resulted from infection during or following abortion. In four, quite positive evidence of gonorrhœa was ascertained to have been the cause of infection and suppuration. In four, the abscess formed soon after delivery at term, and was due to puerperal sepsis. The source of infection in the remaining cases could not be ascertained.

The amount of pus in these cases varies greatly, from a small quantity to a quart or more. The quantity of pus does not always indicate the extent of disease or bear direct relation to the prognosis.

* Read before the First Pan-American Medical Congress.

In more than one case the remnants of ovaries and tubes removed were but slight evidence of the severity of the operation, or the very critical condition of the patient. In not one case could the pus have been reached satisfactorily by aspiration.

The list includes—with two exceptions—all cases of pelvic abscess occurring in my service during two years. In one of the cases, not mentioned, occurring in a private patient, the abscess was low enough to be reached by vaginal incision and drainage. She recovered and improved greatly, notwithstanding the presence of the diseased appendages, which remain and threaten a repetition of the suppuration on the other side. In the other *exception* the patient would not consent to operation when requested, left the hospital, and returned in a week ill with peritonitis, which was not relieved by vaginal incision or later by abdominal flushing. The operation in nearly every case involved the separation of omental adhesions from the anterior abdominal wall, as well as from the uterus, bladder, and upper wall of the abscess and intestines. In at least two the omentum was tied off entirely across the lower border.

The abscess wall consists of Falloppian tube, ovary, broad ligament, pelvic wall, omentum, mesentery, uterus, and Douglas's *cul-de-sac*, and involves the bowel in some instances nearly to the umbilicus. In no case was the pus found within the broad ligament. The tube and ovary, having been the first to receive the infection, are generally distorted and even disorganized, in some instances forming but a small portion of the abscess wall.

No. 67, a pyæmic mesenteric abscess, had developed without apparent infection of either tube or broad ligament.

Result of Operation in Pelvic Abscess.—Severe shock generally follows an operation in each case. This has been anticipated as far as was possible by the administration of heart tonics and stimulants. Usually an hour is required to complete the operation in so formidable an undertaking. The temperature is generally reduced by section, and is often subnormal and very unreliable, as it fails to indicate correctly the extent of sepsis or inflammation. The pulse is generally quick, often reaching 140 or more, and is indicative of shock and exhaustion.

These symptoms of shock may continue for two or even three days; then, if the bowels are open, the patient rapidly recovers.

With the exception of the opium habit in one case, which was formed during the many months of suffering the poor woman experienced prior to section, I know of nothing but perfect results in the cases of patients surviving laparotomy for pelvic abscess.

One woman has, since her recovery, returned to the lying-in department of the hospital and safely given birth to a child at term.

Pyosalpinx, Tubo-ovarian Abscess, Hydrosalpinx, Cystic Ovaries.—In twenty-seven of this list of thirty-four cases pus was present and poured out of the abdominal incision when the pus sac was ruptured, or when the separation between the distal extremity of the tube and the ovary occurred, which often happens when a tubo-ovarian abscess

is removed. In the other cases no free pus was present. Two of these were purely hydrosalpinx with cysts of the corresponding ovary. The others were large cysts of the ovary, in one instance containing a pint of fluid. In each case the contents were regarded as infectious. The infection in each case had entered the tube and been communicated to the ovary through the uterine mucosa. No positive evidence of tubercle could be ascertained in any case.

In thirteen the disease was a result of gonorrhæal infection. In the other pus cases infection was nearly always found due to septic abortion. In a few no cause could be ascertained.

A rise of temperature was observed in nearly every pus case prior to section. The pulse was generally quick, and pelvic examination revealed pelvic peritonitis with the ever-present fixation of the uterus and more or less distinct masses on either side of the uterus or filling the pelvis entirely.

Immediate Result.—In this list two deaths occurred. The first was due to an unsuspected pyæmic uterus from a "missed abortion." The patient had only a cystic ovary removed and did not have pyosalpinx. The other death was due to shock following section. This patient, a German Jewess of poor intelligence, had previously been treated in the hospital for mammary abscess. She was discharged well. In a week she was back with a severe attack of peritonitis, feeble pulse, great pain, and high temperature. She improved again, and when an operation was finally determined upon another attack of peritonitis occurred which the operation failed to relieve. The favorable moment in this case was lost. The patient resisted every measure taken for her relief and insisted upon vomiting or otherwise discharging all food and medicine given for her relief. There should be hardly any mortality in these cases.

Final Result.—However much disputation there may be as to the propriety of abdominal section for nervous or mental disease due to ovarian degeneration or irritation, there can be very little plausible objection to operations for pus. The final result is, as a rule, very satisfactory. Some women have all the symptoms due to menopause after the removal of large ovarian abscesses which have existed for months, and which leave no visible remnant of the ovary to be recognized as such. There may be a mere shell or thin sac left, yet menstruation may continue at regular intervals before and after the operation.

These consequences, of however great importance, should not and do not deter the surgeon who operates to save life or even to prevent invalidism. I am quite of the opinion that no surgery is of more importance, or attended with better results in every way, than that for the suppurative pelvic disease of women.

Nos. 21, 35, and 50 required a second operation in each instance. No. 21, a blood cyst of the ovary, right side, was removed with great difficulty. The left ovary was so small and concealed by adhesions that I could not find it. It grew to form another blood cyst, which I removed some months later. No. 78: I found the viscera transposed in this case, the appendix on the left side.

No. 35 had oophorectomy done, removal of hydrosalpinx, etc., for menorrhagia and pain, and afterward required vaginal hysterectomy for sarcoma of uterus.

No. 50: a sinus opened up and infected ligature removed, which was used in tying off a small myoma attached to the fundus uteri.

With the above-mentioned exceptions, I know of nothing in any of these cases but a perfect result.

The author rarely finds a case for operation in the stage of primary inflammation. If surgeons generally can detect a salpingitis early enough to prevent a gonorrhœal infection of the peritonæum by a resort to salpingectomy, such practice I should consider correct, but it has not been my experience to find these cases in hospital or even other practice. The suppurative stage is reached and the case is no longer one requiring hot douches, iodine applications, etc., but demands surgical treatment. In short, I consider salpingitis of infectious character of short duration, and not often do many days elapse before pus has formed, when it is practically no longer a salpingitis but a pyosalpinx—an abscess.

Oophorectomy for Myoma.—As may be seen in the summary, only twice have I operated with the intention of checking the growth of uterine myomata. In one case—in a young lady—the operation was easily done and gave a very good result. The tumor is not growing and her mental condition, which was very greatly disturbed, has improved until, in fact, she is quite well. She ceased to menstruate, and I think the operation will prove a success.

In the other case a negress had a large pelvis-bound myoma with suppurating tubes and ovaries, which were with great difficulty removed. The patient had unexpected mania for two weeks, beginning a week after the operation. She recovered from the operation and returned to her home, lived about a year longer, and I have not learned the cause of her demise. This case is the only one in which I have considered the removal of the tumor an impossibility. It is probable that the patient would have died under the operation had entire removal been attempted.

Vaginal Hysterectomy.—Only three cases of uterine carcinoma were thought favorable for complete extirpation. In nearly every case sent me by physicians the disease was found already too far advanced to hope for a complete extirpation and eradication of the disease.

My earlier experience (1886 to 1888) with this operation was confined to cases of which I can say nothing but that it was not good practice to attempt complete extirpation in such advanced disease.

In one case (No. 81) the uterus was removed for proclivencia.

Silk ligatures were used in each case. The operation is quite an easy one, and should be frequently performed if cases are found sufficiently early. In each case the recovery was comparatively uneventful. One case required the combined abdominal and vaginal method, the bladder being torn in the operation, it being apparently softened by disease. It was immediately sutured, and the patient had perfect healing in every respect before she left the hospital.

Batley's Operation.—In all cases where the ovaries were

removed for the purpose of curing pain, producing an artificial menopause, or preventing impending insanity, it has been the unvarying custom of the author not only to have careful consultation with his *confrères* as to the propriety of the operation, but to know beyond a reasonable doubt that other means of cure have been satisfactorily tried. In nearly every case, in addition to this, some abnormal condition—such as enlargement, prolapse, or other result of chronic disease—was discovered before the operation. Five cases of this list come under this heading. All the patients recovered from the operation. One of them, operated on for incipient insanity, recovered well and has been able to attend to the duties of her profession constantly since that time. Another, the second, appeared greatly benefited at first, but in six months committed suicide. I regret to say that I was deceived in this case by the friends and physician of the patient, who failed to tell me of her previous attack of insanity. A third case was not in the least influenced by a double salpingo-oophorectomy (one ovary being quite large from cystic degeneration).

The other patients had suffered great pain, and were anxious to have something done for them at any risk, and, although the operation was done after due trial of other remedies and because some disease was believed to have been present, yet it was attended with but poor result, as they are (two of them) still complaining.

Uterine Myomata.—Eleven supravaginal hysterectomies for myoma, with three deaths. One death was due to hæmorrhage from a wounded mesentery in a case of complete extirpation (tumor, twenty pounds). The two other patients died of shock and obstructed bowels, with very little evidence of peritonitis, five days after the operation. Three operations were completed by using the wire clamp; one death occurred. Three by the ventrofixation method; one death. Four by complete extirpation; one death. One large, soft, parasitic myoma, operated upon by the Schroeder method, ended in recovery.

My experience leads me to the conclusion that if operators select only such cases as are no longer able to work, and who have very large tumors with great pain—which is almost positively due to severe complications—just so long will the mortality from hysterectomy be high. *Per contra*, if a diagnosis could be made while the growth is still within the pelvis, and the patient sent to the surgeon for operation before complications—adhesions to viscera, etc.—arise, the mortality would be greatly reduced.

In nearly all of my cases severe difficulties were encountered which greatly prolonged operation, and to this I attribute the mortality. Of the eleven hysterectomies, nine were done for colored women. Two patients were white and made good recoveries. This shows a death-rate in negroes of thirty-three per cent. I do not consider them good subjects for surgery.

Hysterorrhaphy (Ventrofixation).—This operation was done in seven cases for prolapse or retro-displaced uteri, and in two of them prolapsed, adherent, or diseased ovaries were removed. One death occurred which should be charged against the operator or assistants, not the method. In this case a diseased and prolapsed ovary was removed without

thought of infecting the cavity of the peritonæum, yet peritonitis quickly developed and carried off the patient. I have abandoned Alexander's operation for ventrofixation. The latter operation is easy of performance and should give no mortality. Three buried silkworm-gut sutures are used to anchor the uterus to the abdominal wall, which in each case have given no trouble and perfectly satisfactory results.

The author has given the names of physicians as reference who were formerly or are at present either the medical attendant or who know the history of the patient since operation. He also takes pleasure in inviting any who desire full particulars of any case herein mentioned to call upon Dr. J. T. Kelly, resident physician of Columbia Hospital, my valued and very competent assistant, who will answer any inquiry.

No.	Age.	Disease.	Cause.	Result.	Drainage.	Remarks.	Date.	Reference.
1	37	Salpingitis, ovaritis, etc.	Pelvic peritonitis.	Recovery.	Yes.	Had been an invalid for years.	11, 24, '88	Dr. Hicks.
2	26	Tubercular peritonitis.	Tubercular appendages.	Died, five days.	"	Repeated attacks of peritonitis for years.	12, 15, '88	I. S. S.
3	27	Tubercular kidney.	Recovered from operation.	"	Nephrotomy.	11, 17, '88	I. S. S.
4	38	Hysteria, incipient insanity.	Suspected ovarian disease.	Improvement, satisfactory result.	No.	Salpingo-oophorectomy; patient attends to usual duties.	7, 5, '89	I. S. S.
5	33	Hysteria, menorrhagia, pelvic pain.	Cystic ovaries.	Cure.	"	Salpingo-oophorectomy.	11, '89	Dr. Christian.
6	35	Menorrhagia, impending insanity.	"	First, improvement; suicide later, six months.	"	"	6, 16, '90	I. S. S.
7	35	Ovarian cyst, fifteen pounds.	Dermoid.	Recovery.	Yes.	Many slight adhesions.	7, '90	Dr. Taylor.
8	29	Cyst of ovary.	"	"	Cyst ten ounces; omental adhesions.	9, 11, '89	I. S. S.
9	40	Myoma uteri.	In negress.	"	No.	Wire clamp.	11, '90	Dr. Hoge.
10	30	"	"	"	"	Ventro-fixation; ten-pound growth.	5, '91	Columbia Hospital.
11	40	"	"	Sinus left from ligature.	"	Sinus permits pseudo-menstruation from stump of uterus.	6, 1, '91	Do.
12	45	"	"	Recovery from operation.	"	Twenty-pound tumor adherent to everything; patient in <i>extremis</i> several days; recovery from operation. Mental condition very unsatisfactory before and after operation.	6, 11, '91	Do.
13	35	Parasitic soft myoma, eighteen pounds.	White patient.	Perfect cure.	Yes.	Dropped pedicle, which was from right broad ligament; only a small slender pedicle from original uterine origin, near fundus.	6, 18, '91	I. S. S.
14	32	Retroflexion, disorganized appendages.	Old chronic inflammation.	Recovery.	No.	Patient had been an invalid for several years.	7, 2, '91	Dr. Gott.
15	30	Hystero-epilepsy, pelvic pain, large ovary, salpingitis.	Pelvic peritonitis.	Cure of pelvic pain, not of neurosis; improvement.	"	Improvement in health; now able to work.	7, '91	Columbia Hospital.
16	28	Pelvic abscess.	Puerperal infection at term.	Recovery.	Yes.	Patient sick eight months (septicemia) before operation.	8, '91	Do.
17	..	Extra-uterine pregnancy.	Died.	Patient in collapse all day before operation. Fourth month, hemorrhage outside sac without rupture.	9, '91	Do.
18	20	Suspected tubercular peritonitis.	Recovered from operation and symptoms improved.	Yes.	Exploratory operation.	9, '91	Do.
19	32	Pyosalpinx, chronic salpingitis and ovaritis.	Pelvic peritonitis.	Recovery.	No.	Extensive adhesions.	10, 5, '91	Dr. Carr.
20	..	Pyosalpinx.	Gonorrhœa.	"	"	Tubes like sausages.	10, 15, '91	Columbia Hospital.
21	30	Blood cyst of ovary.	Temporary relief.	Yes.	Patient did well for a time, then returned (see No. 78). One ovary not found.	10, 26, '91	Dr. Moran.
22	46	Fibro-myoma uteri, eighteen pounds.	Negress.	Died fifth day, shock; bowel obstruction, acute yellow atrophy of liver.	"	Ventro-fixation; myomata in both broad ligaments.	11, 9, '91	Columbia Hospital.
23	30	Pelvic abscess, many ounces of pus.	Gonorrhœa.	Died fifth day, uræmia.	"	No peritonitis after operation; nephritis from specific infection.	11, '91	I. S. S.

No.	Age.	Disease.	Cause.	Result.	Drainage.	Remarks.	Date.	Reference.
24	21	Pelvic abscess.	Gonorrhœa.	Recovery, sinus from ligature; afterward closed.	Yes.	Appendages and entire pelvis filled with pus.	11, '91	I. S. S.
25	35	"	"	Recovery.	"	Tumor nearly to umbilicus.	11, 30, '91	Do.
26	32	"	Abortion, infection.	Died twenty-four hours, shock.	"	12, '91	Do.
27	34	Cyst of ovary.	Recovery.	No.	Cyst filled pelvis; everywhere adherent.	1, 4, '92	Do.
28	30	Pyosalpinx.	Gonorrhœa.	"	"	Tubes like sausages; patient ill sixteen years.	1, 7, '92	Dr. Ritchie.
29	24	Hydrosalpinx.	"	"	"	Chronic pelvic peritonitis.	1, 18, '92	Columbia Hospital.
30	27	Pelvic abscess.	Abortion.	"	Yes.	Tumor-like fibroid of uterus to umbilicus.	2, 4, '92	Do.
31	40	Fifty-pound double ovarian tumor (multilocular broad lig. cyst).	Recovery from operation.	"	In nine months abscess formed under broad ligament (see No. 74).	2, 8, '92	Do.
32	24	Pyosalpinx, tubo-ovarian abscess.	Recovery.	"	Pelvic organs all adherent <i>en masse</i> .	2, 10, '92	Dr. Bowen.
33	25	Pyosalpinx.	Gonorrhœa.	"	No.	Easy operation and recovery.	2, 15, '92	Columbia Hospital.
34	19	Pelvic abscess.	Abortion.	Died.	Yes.	Shock, third day.	2, 17, '92	Do.
35	25	Pyosalpinx, menorrhagia.	Recovered.	No.	Patient had uterus removed afterward for sarcoma (see No. 80).	2, 22, '92	Do.
36	36?	Insanity, cystic ovary.	Recovered from operation easily; mental symptoms not improved.	"	Patient in asylum.	2, 24, '92	I. S. S.
37	40	Ascites.	Movable kidney.	Recovery.	Yes.	Movable kidney not suspected until abdomen was opened.	2, 24, '92	Columbia Hospital.
38	50	Dermoid cyst of ovary, twelve pounds.	"	"	Cyst ruptured a month before operation, everywhere adherent; twisted pedicle; nephritis.	2, 27, '92	Dr. Frost.
39	23	Cystic ovaries, retroflexion and old salpingitis.	"	No.	Operation very difficult, owing to adhesions.	2, 29, '92	Columbia Hospital.
40	..	Cystic ovaries.	"	"	Ovaries size of hen's egg.	3, 2, '92	Do.
41	..	Fibro-myoma uteri, twenty pounds.	Negress.	Died third day, shock.	"	Extra-peritoneal method.	3, 5, '92	I. S. S.
42	27	Tubo-ovarian abscess.	Gonorrhœa.	Recovery.	Yes.	Bowel involved; fimbria adherent to intestine; necrosis.	3, 7, '92	Dr. C. G. Stone.
43	28	Myoma uteri, pyosalpinx (pus sacs removed).	Negress?	Recovered from operation.	No.	Patient had mania after operation; the tumor was not removable; patient died about a year later.	3, 19, '92	Dr. Gibson.
44	20	Prolapsus uteri and ovary.	Nullipara?	Improved.	"	Hysterorrhaphy.	3, 28, '92	Columbia Hospital.
45	..	Pelvic abscess.	Abortion, gonorrhœa.	Recovery.	Yes.	Omentum, bowel, appendages glued together and large quantity pus present.	4, 9, '92	Do.
46	40	Cyst of left kidney, forty-eight ounces.	Blood cyst.	"	"	First suspected sarcoma, but no recurrence; patient perfectly well; sutured sac to abdominal wall.	4, 16, '92	Do.
47	20	Pelvic abscess.	Puerperal septicæmia.	Recovery; patient insane for a time after return home.	"	The only fecal fistula in my first hundred cases; fistula closed spontaneously; patient well.	4, 20, '92	Dr. Ewing.
48	24	Pelvic abscess, from puncture or rupture of uterus.	Infection by midwife.	Recovery.	"	Intestinal necrosis; many sutures required; easy recovery after second day.	4, 30, '92	Dr. Moran.
49	38	Unsuspected septic uterine contents (abortion), cystic ovary removed.	Abortion, pyæmia.	Died thirty days.	No, not at first; afterward gauze.	The uterus was large, very pale, and soft, but did not know its contents at time of operation.	5, 7, '92	Dr. Smith.
50	..	Pyosalpinx, tubo-ovarian abscess.	Infection.	Recovered.	Yes.	Small fibroid removed from fundus uteri; infected sinus, afterward ligature removed.	5, 9, '92	Columbia Hospital.
51	40	Pelvic pain, uterine prolapse.	Cystic ovaries; relaxed ligaments.	Recovered from operation easily, improvement in health not well.	"	Chronic neurasthenia.	5, 11, '92	Dr. Nourse.
52	24	Pyosalpinx, cystic ovaries.	Gonorrhœa.	Recovered.	Yes.	6, 11, '92	Columbia Hospital.
53	26	Pyosalpinx, tubo-ovarian abscess.	"	Recovery.	"	Several ounces of pus.	6, 15, '92	Do.

No.	Age.	Disease.	Cause.	Result.	Drainage.	Remarks.	Date.	Reference.
54	26	Fibro-myoma uteri size of large cocoon; nut, mental symptoms.	Mind quite restored; tumor greatly lessened in size at present time.	No.	Salpingo-oophorectomy; easy operation and recovery.	6, 18, '92	I. S. S.
55	32	Tumor of gall-bladder size of large orange.	Gall stones.	Many stones found, sinus remained since closed.	Yes.	Patient returned, and further search for stones (4, 15, '93); cured.	6, 18, '92	Dr. C. G. Stone.
56	..	Retroflexion of uterus, pain and dyspareunia.	Uterus in good position, not otherwise quite well.	No.	A cyst of ovary excised, sepsis of wound; no pelvic pain at present.	6, 11, '92	I. S. S.
57	45	Large myomatous tumor, 20 lbs., filling entire cavity; pregnancy, 4th month, not suspected.	Negress.	Died third day, hemorrhage from mesentery.	Yes, tube and gauze.	Complete extirpation; easily done save for attachments to mesentery, which were severely injured.	6, 29, '92	Columbia Hospital.
58	35	Sarcoma uteri, entire uterus involved; tumor nearly to umbilicus, five pounds.	Patient had an intra-uterine fibroid removed a year previous; recurrence eight months afterward.	Recovery without incident ten months since; better health than for years.	Yes, tube and gauze.	Complete extirpation of uterus, ovaries, etc.; patient has gained many pounds of flesh.	7, 13, '92	Dr. Ames.
59	..	Pyosalpinx, one fimbria attached to intestine; necrosis and danger of rupture; omentum necrotic and large amount of it removed.	Infection.	Recovery from operation, and last report quite well.	Yes, tube and gauze packing.	The tube had adhered to bowel as high as crest of ilium, six inches from cornua of uterus.	7, 20, '92	Dr. Smith.
60	60	Cancer of uterus.	Recovery; bladder involved, afterward closed; well nearly one year after.	Yes, <i>per vaginam</i> .	The growth was not primarily of cervix, but of middle portion at and above the internal os.	7, 28, '92	Dr. Hicks.
61	23	Suspected hemorrhage, intra-abdominal.	Abortion.	Recovery without incident.	No.	Patient in collapse when brought in hospital; amount of blood very uncertain, hence the exploratory opening.	9, 1, '92	Columbia Hospital.
62	..	Intra-abdominal hemorrhage.	Suspected extra-uterine pregnancy.	Recovery.	Yes.	Abdomen distended with blood; no foetus found.	9, 3, '92	Do.
63	..	Old sinus, from infected ligature (see No. 50).	After removal of small fibroid ligature infected.	Sinus closed.	No.	9, 10, '92	Do.
64	..	Suspected pyonephrosis or calculus of ureter, cystitis.	Nothing found.	"	Patient had been an invalid, and hence the exploration.	9, '92	Do.
65	..	Pyosalpinx, tubo-ovarian abscess.	Infection.	Recovery.	Yes, gauze and glass tube.	Aristol over adhesions; perfect result.	9, 17, '92	Do.
66	23	Pyosalpinx.	Gonorrhoea.	"	Yes.	Normal recovery.	9, 22, '92	Do.
67	28	Pyemic abscess, limited to bowels and mesentery.	Abortion, sepsis.	Died third day.	"	Operation had no effect in minimizing sepsis; tubes not enlarged.	9, 24, '92	Dr. C. G. Stone.
68	32	Myoma uteri, twelve pounds.	Negress.	Recovered.	"	Complete extirpation.	10, 12, '92	Columbia Hospital.
69	32	Ovarian cyst, fifteen pounds.	"	"	Multilocular cyst.	10, 8, '92	Dr. Walsh.
70	33	Pelvic abscess, size of cocoon; right tubo-ovarian abscess.	Puerperal septicaemia, eleven months since last child.	"	Yes, gauze and tube; much hemorrhage.	This case was in a morphia habitué; critically ill for a week after section.	10, 12, '92	Dr. Beaty.
71	33	Pelvic and ovarian pain, cystic ovary, right side, removed.	Recovered from operation, symptoms just as before.	No.	Neurasthenic case.	10, 22, '92	Dr. Speiden.
72	..	Retroflexion, cystic ovary removed.	Recovery.	"	Hysterorrhaphy, ovary prolapsed and held under the uterus.	10, 22, '92	Columbia Hospital.
73	..	Pelvic abscess, opened prior to operation.	Abortion.	"	Yes.	Disorganized appendages.	10, 26, '92	Do.
74	40?	Pelvic abscess, extra-peritoneal.	"Adenoid" growth below broad ligament.	Died two days, shock and sepsis.	"	See case No. 31. Had ovariectomy done, both broad ligaments removed.	10, 29, '92	Do.
75	39	Old salpingitis and ovaritis.	Pelvic peritonitis.	Recovery.	No.	Uneventful recovery.	11, 5, '92	Dr. Love.
76	19	Congenital displacement of ovaries, salpingitis.	"	"	Batley operation; normal convalescence.	11, 5, '92	Columbia Hospital.
77	21	Pelvic abscess, septic peritonitis.	Abortion, sepsis.	Died, shock, third day.	Yes.	Should have merely washed out abdomen instead of completing operation (forty minutes).	11, '92	Do.

No.	Age.	Disease.	Cause.	Result.	Drainage.	Remarks.	Date.	Reference.
78	..	Blood cyst of ovary, transposition of viscera.	Pelvic peritonitis.	Recovered from operation.	Yes.	Appendix found on left side; general adhesions throughout pelvis, including intestines, uterus, bladder, etc.	11, 12, '92	Dr. Moran.
79	26	Suspected abdominal pregnancy, high temperature, hemorrhage from bowels, etc.	Relaxation of uterus gave effect of child floating in abdominal cavity.	All symptoms subsided; subsequent delivery <i>per vias naturales</i> .	No.	Temperature to 105° day before section; two discharges of blood from bowels; patient had been curetted and cervix closed since pregnancy suspected.	11, 13, '92	Dr. Walsh.
80	..	Uterine hemorrhage, sarcoma uteri, previous operation (see No. 35).	Recovered from operation.	Yes.	Patient still has some vaginal hemorrhage. (Since the above, patient well.)	11, 17, '92	Columbia Hospital.
81	25	Procidencia, cysto-rectocele.	Excessive childbearing.	Perfect result.	No.	Hysterorrhaphy, ventro-fixation.	11, 19, '92	Do.
82	40	Pelvic abscess.	Infection?	Recovery.	Yes, gauze and tube.	Large amount of pus; perfect result.	12, 1, '92	Dr. Bovee.
83	..	Pyosalpinx, ovarian and pelvic abscess.	Gonorrhœa.	"	Tube and gauze.	Perfect result.	12, 3, '92	Columbia Hospital.
84	26	Pelvic peritonitis, pelvic abscess.	"	Patient very ill at time of operation; narrowly escaped death by shock, then quick recovery.	Gauze and tube.	Patient ill only two weeks since first attack of specific vaginitis.	12, '92	Do.
85	22	Pyosalpinx, tubo-ovarian abscess.	"	Recovery.	Yes.	Easy recovery; some doubt as to all of right tube having been found.	12, 28, '92	Do.
86	53	Procidencia, cysto-rectocele; ovarian cyst, six ounces.	Slight return of cystocele.	"	Vaginal hysterectomy. This woman without sufficient intelligence to take care of herself.	1, 7, '93	Do.
87	65	Carcinoma uteri.	Recovery from operation uneventful.	"	Negress, vaginal hysterectomy.	1, 14, '93	Dr. Hicks.
88	42	Tubo-ovarian abscess, opening into bowel; pelvic abscess.	Puerperal infection, twelve years since.	Recovery without incident.	Tube and gauze.	Opening into bowel found and sutured; large quantity of pus; aspirated, and sac enucleated.	1, 18, '93	I. S. S.
89	34	Inguinal hernia; previously operated upon in Chicago.	Recovery.	No.	Radical cure; removal of sac and omentum; buried silk-worm sutures.	1, 28, '93	Columbia Hospital.
90	..	Sp. salpingitis; tubo-ovarian abscess.	Gonorrhœa.	"	Yes, tube and gauze.	Bowel severely involved; necrosis; perfect result.	1, 25, '93	Do.
91	26	Retroflexion, hydrosalpinx, cyst of ovary.	Recovery after severe illness.	No.	Should have used drainage; patient had peritonitis; the ovarian cyst contained highly infectious serum.	1, 28, '93	Do.
92	35	Pelvic abscess, pelvic peritonitis.	Many abortions, repeated attacks of peritonitis.	Died three hours after completing operation.	Patient could not take anesthetic satisfactorily; morphine habitué; operation done under many disadvantages; had long suffered from bowel obstruction, etc.	1, 28, '93	Dr. Pool.
93	39	Ovarian tumor; ascites, eighteen pounds; hydrothorax.	Recovery from operation; dropsical symptoms not yet relieved; patient in fairly good health.	Yes, for three weeks.	Large left ovarian multilocular cyst; small right cyst thirty-two ounces; suspected malignant disease.	1, 30, '93	Columbia Hospital.
94	50	Procidencia, cysto-rectocele.	Recovery.	No.	Hysterorrhaphy; ventro-fixation; buried silk-worm sutures.	2, 1, '93	Do.
95	15	Ovarian tumor, twenty pounds.	Recovery uneventful.	Yes.	Twisted pedicle.	2, 5, '93	Dr. Batson.
96	33	Myoma uteri, four pounds.	Negress.	Recovery.	"	Complete extirpation by abdominal method.	2, 11, '93	Columbia Hospital.
97	32	Tubo-ovarian abscess, pyosalpinx.	Gonorrhœa.	"	"	2, 16, '93	Dr. C. G. Stone.
98	35	Tubo-ovarian abscess, pyosalpinx.	"	"	"	Patient had been ill since first attack of gonorrhœa; result far better than expected; complete and satisfactory cure.	2, 20, '93	Columbia Hospital.
99	30	Retroflexion uteri, cystic right ovary.	Died.	No.	Patient unexpectedly developed peritonitis and died; the cystic ovary may have infected the peritoneum.	Do.
100	..	Retroflexion, salpingitis, ovaritis, etc.	Excessive childbearing.	Recovery.	"	Hysterorrhaphy; salpingo-oophorectomy.	Do.

THE CAUTERY IN STAPHYLOTOMY.*

By THOMAS AMORY DE BLOIS, M. D.,
BOSTON.

EVEN so small a subdivision as the uvula is worthy of some special study, although I believe its real utility has never been discovered, yet, like the vermiform appendix, it is unquestionably "there," seemingly unemployed except for evil.

As a complication of pharyngitis, it is, in its state of inflammation, or œdema, decidedly unpleasant; irritating the pharynx, acting as a kind of ball valve to shut off respiration, it makes its presence known constantly.

As the after result of many inflammations, as it hangs limp and flaccid in the pharynx, it is again neither useful nor ornamental.

Although I have never had the opportunity of seeing any of those historical cases of elongation of the uvula, in which it was so long that it could be caught between the front teeth during coughing, yet I have seen it sufficiently long to tickle the epiglottis.

And I take this opportunity of advancing the opinion that elongation of the uvula is a lesion of civilization. I have always held the belief that the "dude was catarrhal," and this is evidently coincided in by the caricaturists of the present day, great students of Nature, who usually depict him with mouth wide open, or else sucking his cane, a continuation of the infantile thumb, which we are told causes the high-arched palate and salient incisor teeth. If you will look back over your professional experience you will, I think, remember that your cases of amputation of the uvula have been generally among the better class of your patients rather than the poorer ones. Thus during a winter's hospital practice of six months I only saw one case (which did not belong there) where operation was indicated,

whereas I might report half a dozen from my office practice—and I did not remove the uvula many times when I should have done so.

The uvula may to a certain extent be toned up and retracted by astringents, faradization, etc.; but if the trouble has been of long standing, removal of a part of the body is certainly indicated. The little operation is certainly one of the simplest, but, as whatever we do had better be done well, I would like to recite to you a little procedure which I have made use of during last winter, not that I suppose it original (for "there is no new thing under the sun").

Troublesome hæmorrhage after amputation, such as our late fellow Dr. Morgan once reported, is very rarely met with; but after snipping with the knife or scissors there sometimes is a quite persistent oozing, which will keep up in spite of all the ice or astringents you can put there. Then, again, the uvula may be very thick and large and would seem to indicate large vessels, a good deal of muscle, and more after-sloughing than one cares for. It was just such a condition of things as this which induced me to operate on A. B., on December 6th, with the galvanocautery.

Many applications with a twenty-per-cent. solution of cocaine were first made until the part had become blanched and was apparently anesthetized; then, placing a tongue depressor on the tongue and giving it to the patient to hold, I passed a fixed loop of platinum wire around the uvula rather high up, for I observed that the cocaine had retracted it.

As soon as the cautery was felt on the posterior surface of the uvula it was drawn tight by the palate muscles, and by pulling in an opposite direction with a forceps I was enabled to bevel the cut very nicely, so that when the wound healed it was well "tapered" and was more of a work of art than the "clubbed" stump which we see after clipping with the scissors. This first patient was a preacher, and his trouble may have been the sequence of ministers' sore throat.

CASE II was that of a lawyer, B. C., on December 17th. He not only talked but smoked; he was something of an athlete, but not robust. I used the cautery with him because I had had a good result with Case I. The procedure was the same. The patient complained of very little pain, but there was the same reflex contraction of the palate. The result was better than before.

CASE III was that of a shopkeeper, on January 30th. This man did not smoke, but used his voice in his business a great deal more than necessary; his uvula was very "dejected." The weather was cold, and I had unfortunately discovered that my gravity battery was useless in cold weather. I therefore had to use a small primary battery and a much smaller loop than before. My current was poor and I had to stop and cocaineize after I had cut through the mucous membrane.

As before, I tapered from back forward, and from the sides toward the point. The result was good; the recovery not delayed.

CASE IV.—I will only weary you with one more case, that of Mr. C. D., a French restaurateur, on February 2d. This was a case of peculiar formation; there appeared to be a kind of permanent erection to the uvula so that it stuck directly to the front; then it twisted to one side with a kind of curl in it like a pug dog's tail. It was difficult to cut properly, and after I had burned through this huge, thick uvula I found that I had beveled the anterior instead of the posterior aspect.

The result after healing was quite good, and I presume that

* Read before the American Laryngological Association at its fifteenth annual congress.

the flavoring of his ragouts went on as well as before. His pharyngitis certainly went on better.

These were done with the fixed loop. Had they been cut with the galvanic snare (which winds on a reel) the cut would of necessity have had a straight surface and not a continuous bevel.

It seems almost puerile to waste so much time on so small a subject, but the artistic stump is well worth the extra trouble.

A NEW OPERATION FOR THE RADICAL CURE OF OBSTRUCTION OF THE NASAL DUCT.

By GEORGE W. CALDWELL, M. D.,
INSTRUCTOR, NEW YORK POLYCLINIC, ETC.

THE passage of too large lacrymal probes is doubtless responsible for many cases of complete bony closure of the nasal duct. The repeated bruising and lacerating of the periosteum lining the canal results in formative periostitis, and in ivory-like exostoses which finally close the canal permanently. In others, contracting cicatrices form a dense fibrous structure which readily closes after each dilatation. Bony obstructions from fracture of the superior maxilla are occasionally met. In these and in other cases where it is impracticable to pass the probe into the nasal space it has been the custom to obliterate the sac and duct by the galvano-cautery or chemical caustics, or by extirpation with the knife, after which drainage from the conjunctival sac must, of course, pass over the face. This is very troublesome to the patient and sometimes excites an eczematous condition which is very difficult to heal under the continued irritation.

It is possible to avoid these complications, and to restore the function of the nasal duct by the operation described in the following case :

J. D. H., aged thirty-five years, appeared at my clinic with dacryo-cystitis and epiphora of three years' standing. In the acute stage the lower canaliculus had been slit and large probes passed at intervals. Since then he has attended different clinics and received the usual treatment of syringing and probing. At length probes could no longer be passed and the destruction of the lacrymal sac was advised. To this, however, he declined to submit. I found complete bony closure of the nasal duct in its lower portion and operated in the following manner, after producing cocaine anesthesia of the nasal duct and the middle meatus of the nose.

The author's lacrymal probe (see *New York Medical Journal*, May 27, 1893) was passed as far as the obstruction and left *in situ*. By means of the electric trephine the anterior tip of the inferior turbinated body was removed as far up as the opening of the nasal duct, when, by cautiously continuing the operation upward, removing the nasal wall of the nasal duct together with the ivory-like new formation, the tip of the probe was reached, establishing again free drainage for the lacrymal sac. The relief of epiphora was immediate, and under antiseptic irrigations semi-weekly the blennorrhoea of the sac rapidly subsided and the wound healed kindly. Six months after the operation the patient reported for examination. The drainage was good. The sac had returned to a healthy condition and the patient considered himself cured.

D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, OCTOBER 21, 1893.

THE SANITARY MANAGEMENT OF "SUSCEPTIBLE" MERCHANDISE.

THE British Government has recently published a document entitled *Correspondence respecting the Sanitary Convention signed at Dresden on April 15, 1893*. It seems that under the convention the term "susceptible"—i. e., susceptible of contamination with infectious material—is of very limited application. It relates only to articles of clothing and bedding that have been in use and to such "rags" as the French call *chiffons* and *drilles*. It was decided that "rags" sent in bulk and under the customary conditions applying to them as an article of merchandise should not be deemed "susceptible," and should therefore be free from all restrictions. The same exemption was made to apply to clean clippings and various similar articles, also to woolen rags known to the trade as *Kunstwolle* and shoddy. It is stated that in the interchanges of views that took place at numerous discussions in committee, in subcommittee, and in more informal gatherings the leading sanitarians present, including Professor Koch, Professor Brouardel, and Professor Proust, were all of the opinion that in no case had cholera been traced to "rags" in their exempted form, and that the risk of their conveying the infection of cholera was so remote as to justify the exemptions specified.

It was further decided that the transit through a country even of merchandise classified as "susceptible" must not be prevented if the goods had been so packed that they could not be handled on the way; that merchandise ought not to be prevented from entering a country even if it had passed through an infected district, provided it had been so conveyed as to avoid contact with infected things; that no merchandise should be subject to restrictions if it could be shown that it had been dispatched from an infected country not later than five days before the beginning of an epidemic; and that no merchandise ought to be retained in quarantine at land frontiers.

The "rags" and similar goods that are exempted are: 1. Rags compressed by hydraulic force, transported as wholesale merchandise in bales surrounded by iron bands, with marks and numbers showing their origin and accepted as such by the authorities of the country of destination. 2. Clean clippings (*déchets neufs*) coming directly from spinning, weaving, making up, or bleaching establishments, artificial wool (*Kunstwolle*, shoddy), and fresh paper shavings.

Disinfection is to be applied only to such merchandise and goods as the local sanitary authorities may consider contaminated and to such merchandise and goods as might otherwise be prohibited from importation. The authorities of the country of destination are to settle the mode and place of disinfection,

but it must be carried out in such a manner as to damage goods as little as possible. It is left to each country to settle the question of compensation for damage due to disinfection. Letters and correspondence, printed matter, books, newspapers, business documents, etc. (not including postal parcels), are not subject to any restriction or disinfection.

MINOR PARAGRAPHS.

CEREBRAL LOCALIZATION IN THE EIGHTEENTH CENTURY.

DR. FARABEUF quoted in the *Gazette hebdomadaire de médecine et de chirurgie* for July 9th an interesting passage contained in a volume based on observations made in Vienna between 1746 and 1750 by Joseph Baader, professor at Freiburg. The work is entitled *Observationes medicae, incisionibus cadaverum anatomicis illustratae*. The passage reads, translated, "If we now carefully compare the lesions found on the cadaver with the symptoms noted during life, we are able to deduce three facts of value in medical practice. Primarily, the elements and the action of the brain undergo deossation, thus the sensation and motion of one side of the body are dependent upon the action of the opposite cerebral hemisphere; the contrary is also true. How if a patient suffers on the right side of the head, and an abscess forms on that side, the hyperæsthesia and the convulsions always affect the left arm. In the second place, it becomes evident to us that from numerous observations collected with care and attentively compared we are able to determine and indicate, to the great advantage of practitioners, what portion of the brain controls the sensibility and motion of this or that member; in other words, knowing the member affected, we may determine what portion of the brain is diseased, and, inversely, being given a determined lesion of the brain, we may predict the member that will be affected. Thus in one patient the pain and abscess were situated under the right parietal bone, and the convulsions affected the left arm. Then in observation XXV, a young man having paralysis and contractures of the right side had two tubercles of the dura mater beneath the parietal bone, and in the left cerebral hemisphere between the anterior and middle lobes there were hydatids, or better "plagmatides." Perhaps after comparing many such observations we should be able to conclude with certainty that the region of the brain located beneath the parietal bone controlled the mobility and sensibility of the upper extremity of the opposite side."

THE VALUE OF EXPERIMENTAL TUBERCULOSIS IN DIAGNOSIS.

THE *British Medical Journal* for September 23d contains a valuable paper by Professor Sheridan Delépine, in which he reports the results of his investigations of Villemin's method of subcutaneous inoculation of tuberculous matter as a means of diagnosis. Villemin's careful studies, that were published in 1865, showed that his method was capable of giving most definite and reliable results within a short time. Vernil and Clado, in a paper read before the Congress for the Study of Tuberculosis held in 1888, showed that the space of time was shorter than was generally supposed to be necessary; Professor Delépine confirms this. He calls attention to the fact that hunting for the tubercle bacillus in specimens in which the bacilli are scanty is a long, tedious, and discouraging search. Moreover, a negative result where the clinical symptoms point distinctly to a tubercular process is likely to make one disregard

the results of the microscopical examination. He has found that products containing even a small number of tubercle bacilli will, when inoculated under the skin of the inner aspect of the leg of a guinea-pig at the level of the knee, cause tuberculosis of a certain number of organs in the following order: During the second week, of the lymph nodes on the same side of the body below the diaphragm and the spleen; during the third week, of the liver and of the mediastinal and bronchial ganglia; during the fourth week, of the lungs and of the cervical and axillary ganglia; after the fourth week, gradual infection of the lymph nodes of the opposite side of the body below the diaphragm. He concludes that the inoculation method is a diagnostic measure capable of giving results that are free from any ambiguity, and that the negative results that may be obtained by it are nearly as valuable as the positive results, while the latter give more definite information than the discovery of the *Bacillus tuberculosis* in the matter examined. Results should easily be obtained within two or three weeks after inoculation.

THE LATE SURGEON-MAJOR PARKE.

As a memorial to this distinguished Irishman it has been decided to erect a masonic hall in Carrick-on-Shannon, Ireland, to be entitled the Parke Memorial Hall. In a recent notice in this *Journal* his age was stated to be about forty years, but he was less than that—viz., thirty-five. The British Government treated him very badly, and his promotion to the rank of surgeon major he was entitled to from length of service, not as a mark of favor. While a student in Dublin he attended the medical school of the Royal College of Surgeons and the City of Dublin Hospital. A movement is on foot to erect a memorial window in Ballybay Church, in a district where Dr. Parke acted for some time as medical officer. The subscription, which is a nominal one, is confined to members of the medical profession. On the 9th inst. a meeting was held in the Shelbourne Hotel, Dublin, for the purpose of appointing a committee and opening a fund in order to carry out a generally expressed wish that a memorial should be erected in honor of the late Surgeon-Major Parke. Sir George Porter, Bart., moved that, in view of the conspicuous services of the deceased gentleman, it was desirable that a permanent memorial be raised to perpetuate his name and his life work. What form the memorial will take has not at present been determined on, and the matter has been left open. Mr. H. M. Stanley has contributed £50 toward the memorial.

THE ORIGIN OF CIRCUMCISION.

La Médecine moderne states that at a recent session of the Paris Society of Anthropology the question of the origin of circumcision was discussed. M. Letourneau recalled the custom of the Egyptians of practicing phallootomy on the vanquished. This custom still persists in our day among the Abyssinians. Every warrior who has killed an enemy, says James Bruce, presents to the chief a bloody prepucce. The ceremony being concluded, each warrior gets back his bloody trophy, and, taking it home with him, prepares it in the same fashion the Indians employ for scalps. This custom existed among the Hebrews, and to become the son-in-law of Saul David had to bring in the foreskins of a hundred Philistines. Ritual circumcision is thus derived, and was an act of homage to God. The usage of offering portions of the body to the gods has been and is yet very widespread. It is a symbol of a complete sacrifice that has become partial by the lessening rigor of morals. It is thus that blood or the fingers were offered, or the sacrifice of their hair, by the early Christians.

A HOSPITAL NEEDED.

THAT great and ancient city, Damascus, has no hospital for its population of nearly two hundred thousand souls. A successful dispensary has been conducted by the Edinburgh Medical Missionary Society since 1887. It is at present under the charge of Dr. Mackinnon and Dr. Scott Smith. These gentlemen have an Imperial firman granting them power to proceed unmolested in their work and to erect a hospital. The movement is in an initial stage, and the dearth of vacant houses makes the choice of a situation very difficult. If they are obliged to buy land and erect a hospital for sixty patients, together with a dispensary, they estimate that \$25,000 will be required. There is an old saying that where the Englishman would build a fort the Frenchman will erect a theater and the Spaniard a monastery. To this we are tempted to add: and the Scotchman a hospital.

MORE NEWSPAPER MEDICINE.

ONE of the New York newspapers lately gave prominence to a most imaginative article on disease of the vermiform appendix. The writer took the position that operations for that disease were done with unnecessary frequency, and cited a case in which an individual affected with it had declined surgical interference and had ultimately *coughed up* his appendix.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 17, 1893:

DISEASES.	Week ending Oct. 10.		Week ending Oct. 17.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	0	0
Typhoid fever.....	59	11	32	16
Scarlet fever.....	58	3	41	6
Cerebro-spinal meningitis..	3	3	2	2
Measles.....	53	2	63	3
Diphtheria.....	112	34	129	18
Small-pox.....	13	2	20	3

A Warning.—The publishers of this *Journal* request us to warn our readers against a man who sometimes calls himself "E. E. Evans," and who pretends to be the representative of a Chicago company through which, as he avers, he can furnish periodicals at reduced rates. Although the alleged "company" exists only in the imagination of this individual, he has beguiled several of our subscribers into paying money to him on account of the *Journal*, with which he has no connection and for which he is not authorized to collect or obtain subscriptions. All authorized collectors and canvassers for the *Journal* have credentials by which to identify themselves.

The Wayne County (Michigan) Medical Society.—At the recent annual meeting the following officers were elected for the ensuing year: President, Dr. Hal. C. Wyman; vice-president, Dr. E. B. Smith; secretary, Dr. R. H. Honner; treasurer, Dr. C. Henri Leonard; board of directors, Dr. J. E. Clark, Dr. E. W. Jenks, Dr. James Newell, Dr. J. E. Westgate, and Dr. K. Gunsulus.

The Maryland Medical Journal.—Dr. A. K. Bond has resigned the editorship, owing to the demands of his private interests. His connection with that journal, dating from May,

1891, has been marked by ability, dignity, and a progressive spirit. The name of his successor has not been announced.

The Muetter Lectures.—This year's course, on Tuesday evenings from the 17th inst. to December 19th, is to be given by Dr. De Forest Willard, on The Surgical Pathology and Surgery of the Spinal Cord, the Vertebrae, and the Peripheral Nerves.

The Clinical Society of the Elizabeth (New Jersey) General Hospital and Dispensary held its first meeting on Tuesday evening, the 10th inst., and is to hold its meetings on the second Tuesday of each month. Officers have been elected as follows: President, Dr. Victor Mravlag; vice-president, Dr. Alonzo Pettit; secretary, Dr. Norton L. Wilson; treasurer, Dr. E. B. Grier.

The Richmond Academy of Medicine and Surgery.—The special order for the next meeting, on Tuesday evening, the 24th inst., is a discussion on Cerebro-spinal Meningitis, to be opened by Dr. Landon B. Edwards.

Changes of Address.—Dr. Pearce Bailey, to No. 50 East Thirty-first Street; Dr. Hersey Goodwin Locke, to No. 2 West Forty-third Street.

The late Dr. Elijah A. Maxwell.—The Medical Board of Randall's Island Hospital hear with great sorrow of the loss of their associate, Dr. Elijah A. Maxwell. He was for many years a member of this board. Of affable and pleasant manners, he was a warm friend and wise counselor. Therefore, be it

Resolved, That in his untimely death we have lost our most beloved associate, and a break is made in our number which can not be filled. His memory will ever remain among the most pleasant of our lives and will inspire us with an ideal of professional and manly excellence toward which it would be well for us to shape our future lives.

Resolved, That the loss we mourn is not limited to this board, but is shared by the medical profession as a whole.

Resolved, That to his family we tender our warmest sympathy. And be it also

Resolved, That a copy of these resolutions be sent to his family, a copy entered on the minutes of the medical board, and also a copy sent to the medical press.

EDWARD WAITZFELDER, M. D.,
[Signed.] WALDRON B. VANDERPOEL, M. D., } *Committee.*

The Death of Dr. Charles Slover Allen, from typhoid fever, took place in the Presbyterian Hospital on Sunday, the 15th inst. The deceased was a graduate of the Bellevue Hospital Medical College, of the class of 1881.

The Death of Dr. Edward Warren (Bey) occurred at Paris, France, about September 15th. He was a North Carolinian by birth, and was surgeon general of the Confederate corps under General Joseph E. Johnston. He was a practitioner in Baltimore after the late war, and became prominent by reason of his connection with the Wharton case of poisoning, in which his testimony was largely influential in bringing about the acquittal of the accused. Dr. Warren was at that time one of the faculty of the Washington Medical University at Baltimore and of the College of Physicians and Surgeons, in the same city. He afterward took office under the Khedive of Egypt and rose to the rank of surgeon in chief of the Egyptian army. The later years of his life were spent in Paris. He published his personal memoirs in a volume, *A Doctor's Experience in Three Continents*. His contributions to the American medical journals were meritorious. The subjects were largely

surgical. He occupied the surgical chairs in the Baltimore schools above mentioned, and held the chairmanship in surgery of the American Medical Association in 1872. He received the title of Bey from the Khedive in 1882, and was the recipient of knightly honors from at least two other sources. He was in his sixty-sixth year.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 8 to October 14, 1893:*

IRELAND, MERRITT W., First Lieutenant and Assistant Surgeon, Fort Apache, Arizona Territory, is granted leave of absence for one month, to take effect about the 20th inst.

MC CREERY, GEORGE, Captain and Assistant Surgeon, Fort Sidney, Nebraska, is granted leave of absence for one month, to take effect on or about October 15th.

SMITH, ALLEN M., First Lieutenant and Assistant Surgeon, will proceed without delay to Fort Missoula, Montana, and report to the commanding officer of that post for temporary duty, to enable CROSBY, WILLIAM D., Captain and Assistant Surgeon, to take advantage of the leave of absence granted him.

DE SHON, GEORGE D., First Lieutenant and Assistant Surgeon, is relieved from first duty pertaining to the medical section of the War Department Exhibit, World's Columbian Exposition, Chicago, Ill., and will return to his proper station, Fort D. A. Russell, Wyoming.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending October 14, 1893:*

COOKE, GEORGE H., Medical Inspector. Detached from Navy Yard, League Island, Pa., and assigned to special duty at Philadelphia, Pa.

DEER, E. Z., Surgeon. Ordered to Navy Yard, League Island, Pa.

MACKIE, B. S., Surgeon. Detached from duty in Philadelphia, Pa., and to wait orders.

Society Meetings for the Coming Week:

MONDAY, *October 23d*: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, *October 24th*: New York Dermatological Society; Buffalo Obstetrical Society; Medical Society of the County of Putnam (quarterly), N. Y.; Richmond, Va., Academy of Medicine and Surgery.

WEDNESDAY, *October 25th*: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Metropolitan Medical Society (private); Albany, N. Y., City Medical Association; Medical Society of the County of Albany; Berkshire, Mass. (Pittsfield), and Middlesex, Mass., North (Lowell) District Medical Societies; Gloucester, N. J. (quarterly), County Medical Society; Philadelphia County Medical Society.

THURSDAY, *October 26th*: New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopaedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private); Massachusetts Medical Benevolent Society (annual—Boston).

FRIDAY, *October 27th*: Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

SATURDAY, *October 28th*: New York Medical and Surgical Society (private).

Letters to the Editor.

ATHETOSIS.

NEW YORK, *October 9, 1893.*

To the Editor of the New York Medical Journal:

SIR: In your issue of October 7th I note the description of a case of post-hemiplegic athetosis, with illustrations, by Dr. McGillicuddy. Among other things, the doctor says: "It is certainly a rare and interesting condition." Interesting it undoubtedly is, but I should feel it wrong to let the statement as to its rarity go unchallenged. It is not at all a rare nervous affection, and, were neurologists to publish the histories of their cases of post-hemiplegic athetosis with illustrations, the medical press would be deluged and there would be space for little else. Now it never occurred to me to publish an account of the case of M. S., described by the doctor in his article, although she was for several years after he saw her a patient of mine in the New York Hospital for Nervous Diseases on Blackwell's Island. I did make use of the facts in her case to swell the statistics of one hundred and forty-one cases in a paper by Sachs and myself, on The Infantile Cerebral Palsies, published in the *Journal of Nervous and Mental Disease* for May, 1890. Athetosis existed in twenty per cent. of our cases. I have recently had occasion to study carefully the details of two hundred and fifty cases of infantile cerebral palsy observed by myself at the Polyclinic, at the Vanderbilt Clinic, and in Blackwell's Island institutions. Athetosis existed in about twenty per cent. of all the cases of hemiplegia. I think it therefore proper to correct the impression which might be conveyed by the doctor's article that this is an unusual phenomenon. In the last part of his short paper he makes the additional observation that "It is extremely rare in children." The fact is that post-hemiplegic athetosis is much more frequent in the hemiplegias of childhood than in those of adult life.

FREDERICK PETERSON, M. D.

Proceedings of Societies.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Nineteenth Annual Meeting, held in Indianapolis on Wednesday, Thursday, and Friday, October 4, 5, and 6, 1893.

The President, Dr. R. STANSBURY SUTTON, of Pittsburgh, in the Chair.

Fibroid Tumors of the Uterus.—This was the subject of the President's address. After giving a definition of these tumors, the author dwelt upon their etiology, which he said was still a mystery. They were more frequent in the black than in the white race. In both races they were more frequent in the body than in the neck of the uterus, and more frequently situated in the posterior than in the anterior wall. After the menopause was established these tumors generally disappeared, unless they had undergone cystic degeneration. Bearing on this point the President reported an anomalous case. The patient was forty-three years of age; she had never menstruated in her life, had never shown any physiological evidence of ovulation, had been twice

married, and was then a widow and childless. She had for ten years had a large fibromyoma of the uterus, which thus far had given no evidence of atrophy.

With regard to the pathology, the tumor always had its origin in the substance of the uterine wall or in the subperitoneal connective tissue.

The symptoms accompanying the presence of these tumors in various localities and stages of growth were widely different. However, there were vague pain in the pelvic region; pain referred to the front or back of the leg; irritability of the bladder or rectum; uterine tenesmus; menorrhagia or metrorrhagia; dysmenorrhœa; profuse leucorrhœa; and a serous discharge from the uterus. The diagnosis of very small fibromyomata, when many of the leading symptoms were absent, was considered extremely difficult.

So far as the medical treatment was concerned, but little could be done for the relief of patients suffering from fibromyomata, and nothing for those suffering from tumors that had undergone cystic degeneration. Surgically, there were but two routes by which solid uterine tumors could be removed—the vagina and the abdominal wall. With the exception of small tumors with a well-defined pedicle, all subperitoneal fibromyomata could be reached only by section of the abdominal wall. The President had in one case divided the posterior wall of the vagina and through this opening removed the tumor.

SECTION IN GENERAL MEDICINE.

Dr. O. EVERTS, of College Hill, Ohio, Chairman.

Forensic Medicine.—This paper was read by Dr. C. G. COMEGS, of Cincinnati. The author had come to the conclusion, from his experience, that there were but few lawyers sufficiently informed in medical science to conduct a case in the interests of truth and justice, especially the most important cases in medical jurisprudence. Every physician, as an expert witness, must have observed the embarrassment of lawyers in trying medical cases. They asked questions enough, but, from their lack of medical experience, they were incapable of thoroughly understanding the answers of a witness, so that the proper interpretation of them bearing upon the history of a case at the bar might be reached, and, when endeavoring to give the court and jury clear views of the subject by additional questions, they often confused the whole investigation. This disagreeable state of affairs was usually brought about by certain lawyers who had armed themselves by a superficial study of medical works for the occasion. Dr. Comegs believed that the high order of legal men would welcome well-trained men in medicine as coadjutors in the lofty work of establishing justice.

Problems of Public Interest concerning the Insane.—In a paper thus entitled Dr. ORPHEUS EVERTS, of College Hill, Ohio, said there were several problems of public interest involved in the present relations of society to the insane. Among the more important of them were questions of dependency and curability of the insane and the preventability of insanity. The author summarized his conclusions as follows:

1. Intelligent provision for the insane implies provision for various classes, according to the capabilities of enjoyment and the exercise of variously impaired faculties.

2. Public provision for whatever class of insane persons implies housing, clothing, food, sanitary and moral discipline, amusement and employment for such as are capable of being amused and employed, and medical treatment for the sick. The essential features of such provision are adaptability to the needs of each distinctive class.

3. Great, expensive, architecturally imposing palaces, providing alike for all classes, however serviceable they may have

been, æsthetically considered, in times past, as they unquestionably were, are no longer necessary or appropriate to the needs indicated. So long as the insane are comfortably housed, each class according to its condition, it is comparatively unimportant whether it be in large or small houses, cottages, or palaces, connected or detached, in high or low buildings.

4. It is important that the insane of all classes be well fed under careful supervision; but whether in small or large dining rooms, by groups or congregations, is of little consequence; it should be a matter of convenience rather than of number.

5. It is important that public institutions for the insane be well organized and administered.

6. It is wise to retain in office capable men, who have demonstrated their fitness by successful management of affairs, so long as their capabilities continue to be elastic.

Chorea in its Relation to Rheumatism.—This paper was contributed by Dr. I. N. LOVE, of St. Louis. The author said that recently the pathology of this disease had been cleared up to a very considerable degree. It was a definite affection and one especially incident to childhood. The author reported a case of chorea occurring in his practice with a marked history of rheumatism, one of ten cases illustrative of this class observed by him. The cases had not occurred successively. Between them other cases had presented themselves lacking the rheumatic history, but four of the number had occurred in rapid succession, with a pronounced rheumatic history. Seven of the patients had been girls.

Among the exciting causes of the disease were irritation in the nostrils and adenoid growths in the vault of the pharynx, inasmuch as Kirkes, Tuckwell, Hughlings Jackson, and Bastian had supported the embolic theory of the disease, and in consideration of the fact that chorea was so frequently associated with endocarditis, we should be on the alert to interrogate the heart when called to a case of chorea. As matters now stood, we had numerous exciting causes resulting in chorea.

Chorea, its Pathology and Treatment.—This paper was contributed by Dr. H. M. LASH, of Indianapolis. So much uncertainty had existed regarding the pathology of chorea that its treatment had been varied and widely different in its character and aims, amounting even to empiricism. The author then gave the causes of chorea as laid down in the recent work on nervous diseases by Dr. Landon Carter Gray. He referred to the repeated experiments of Dr. H. C. Wood, who had announced his conviction that the choreic movements had their origin in the spinal cord and were directly due to paralysis or depression of the inhibitory function of the cells. Acting on the strength of this conviction, Dr. Wood had sought for a remedy that would strengthen the proper function of these cells, and he had found it in quinine.

Dr. Lash then reported a case of acute chorea in a boy thirteen years of age. The choreic movements had been constant, general, and pronounced. It was agreed to try Dr. Wood's suggestion, and so the patient was put on full doses of quinine. Twenty grains a day, in four doses, were given him for three days, when he showed considerable improvement. The quinine was increased to twenty-five grains a day and given in that amount for three days more, when the patient again reported. There were no remaining symptoms of the chorea, and the quinine was gradually withdrawn. The patient had remained entirely free from the trouble ever since, and without any subsequent treatment of any kind. Another similar case with a successful result was reported.

Diphtheria; its Specific Diagnosis.—This was the title of a paper read by Dr. J. C. CULBERTSON, of Cincinnati. The author said that this disease was of peculiar interest because of its treacherous and insidious character. The uncertainty of diag-

nosis had caused some excellent practitioners to adopt the pernicious habit of diagnosing and treating all cases of sore throat, whether simple or malignant, as if they were true diphtheria. True, the treatment designed for a diphtheria might cure a quinsy, but inestimable harm might be done by causing unnecessary alarm on the part of the patient's family, together with the inconvenience that accompanied isolation of the patient and quarantining of the family, to be followed by the mockery of disinfection of non-infected apartments, and perhaps destruction of clothing and furniture. On the other hand, a case of diphtheria diagnosed as one of amygdalitis might be the cause of breaking up a school or producing an epidemic, with an indefinite amount of sickness and many deaths. A case was cited in point.

Dr. Culbertson then referred to the importance of utilizing the science of bacteriology, and mentioned the plan adopted by the New York City Board of Health of having undertaken to make bacteriological examinations for all practitioners of medicine in that city free of charge.

A Treatment giving a Low Death-rate in Cases of Diphtheria in Hospital and Private Practice.—Dr. WILLIAM A. GALLOWAY, of Xenia, Ohio, read this paper. The paper embraced reports from private practice of physicians who had given the treatment faithful trial during the past three years, who had unhesitatingly commended its value and had all been able to show a death-rate below ten per cent. Immediately the nature of the disease was suspected, the writer gave a grain of calomel for each year of the patient's age up to eighteen, repeated the dose in from four to six hours, and met the action of the mercurial with copious hot-water injections. This treatment was persisted in until the full action of the calomel on the liver and kidneys was obtained, relieving these two important excretory organs of the paretic condition caused by the absorption of the toxalbumin product of the Klebs-Loeffler bacillus. Improvement in the patient's appearance was immediate when the mercurials acted freely. The quantity of foul-smelling grass-green dejecta resulting was astounding. There was no fear of salivation, as under the most heroic use of mercurials no symptom of salivation had been observed by the writer or his friends. Internally, corrosive sublimate was given up to one eightieth of a grain, with full doses of tincture of chloride of iron and alcohol hourly at night and during the day. The topical treatment consisted of the use of peroxide of hydrogen for cleansing the throat, while as an escharotic a solution of twelve grains of salicylic acid in a drachm of alcohol might be used twice a day by the physician only. It had proved of great value in the writer's hands. This escharotic was very powerful and should be used carefully.

The Study of a Fatal Case of Essential Tachycardia was the title of a paper by Dr. JOHN C. SEXTON, of Rushville, Indiana, in which he detailed the symptoms and clinical features of a case of essential tachycardia in which the patient had died after thirty-five days' illness. A peculiar feature of the case had been the response to manipulative efforts, electrical and others, to produce stimulation of the pneumogastric nerve and thus to slow the heart. The paper then reviewed the ordinary symptoms of heart hurry as presented in the literature of the subject, and some further remarks were made concerning the causation, symptomatology, and treatment.

The Address in General Medicine was delivered by Dr. JAMES F. HIBBERD, of Richmond, Indiana. His conclusions were: 1. There is rapid progress being made in preventive medicine. 2. Our present conception of the complicated organization of the human body is based on the theory that the Creator in the beginning endowed vitalized matter with a perpetual law by virtue of which man has been developed, step by

step, from primitive protoplasm. 3. There is no longer an element of doubt in the proposition that the cell is the unit of vital activity, or that all living beings are a single cell or an organization of cells and cell products. 4. The influence of the mind on vital activities, normal and abnormal, is not recognized as it should be, and there is a line of study that would, if properly pursued, dissolve the agnosticism that has in the past embarrassed a knowledge of the reciprocal relations of matter and mind.

(To be continued.)

NEW YORK STATE MEDICAL ASSOCIATION.

Tenth Annual Meeting, held in New York on Monday, Tuesday, Wednesday, and Thursday, October 9, 10, 11, and 12, 1893.

The President, Dr. S. B. WYLIE McLEOD, in the Chair.

The President's Address.—Reviewing the work of the past ten years, the President said that, out of 476 dissertations read before the association, 181 had been on surgery, 153 on medicine, 72 on obstetrics and gynecology, 24 on pathology, 15 on materia medica, 10 on insanity, 8 on ophthalmology, 6 on state medicine, 4 on hygiene, 2 on physiology, and 1 on toxicology. The association had been organized so recently as in 1884, yet it now had a membership of eight hundred and a library containing over nine thousand volumes.

The Association's First Decade.—Dr. JOHN SHREAY, of New York County, followed with an address in which he took up in detail the work of the association during its first decade. He called attention to the fact that a marked feature had been the introduction of prepared discussions—a plan instituted by the British Medical Association and now adopted by many of the more prominent medical organizations. The first discussion of this kind before the association had been suggested by the late Dr. Flint, and it had been on pneumonia. Among the more interesting contributions referred to by the speaker may be mentioned a paper in which was cited the history of what was said to have been the first case of nitrous-oxide anesthesia. The date was given as November 25, 1821, and the subject was said to have been a young man who secretly inhaled a large quantity of the gas from a tank in a room adjoining one in which an exhibition of its properties was being given. Attention was also directed to the learned address by Dr. John W. S. Gouley, of New York, on The Nosology of Disease. Another important paper, on account of its bearing upon the public health, was one by Dr. James G. Porteous, of Dutchess County, entitled Winter Cholera. In this paper it had been shown that the prevalence of this disease in Poughkeepsie was due to the contaminated river water supplied to the town. The author had included some interesting bacteriological examinations of water made by Dr. E. K. Dunham, of New York, and had predicted that in the near future Hudson River towns would have to find some other water supply than that of the river.

The Prevention of Disease was the title of a paper by Dr. JAMES G. PORTEOUS, of Dutchess County. He laid special stress on the diffusion of a better knowledge of the various ways in which tuberculosis was spread, and of the methods best suited to prevent its dissemination. He exhibited a printed card which he distributed to his consumptive patients, which served as a reminder to them and their friends. The patient was directed to spit into a cup or wide-mouthed bottle containing a little carbolic acid and water. This was to be frequently washed out with hot water. The patients were cautioned against spitting on the floor, in the street, or in public conveyances, and against kissing people, and were advised to use individual table utensils, to sleep alone in an airy and sunny room,

and to have separate beds and table linen. The latter should be boiled before being washed. Healthy persons were reminded that consumption was an infectious disease and was communicated principally by swallowing the germs, by inhaling them, or by having them introduced through wounds. They were therefore cautioned against eating or sleeping with a consumptive, using the clothing of such a person, or putting into the mouth coins or other small articles that might have been handled by a consumptive. They were also advised not to kiss on the lips any one who had a cough.

An Additional Note on Nephrotomy and Nephrectomy.—In a paper thus entitled, Dr. E. D. FERGUSON, of Rensselaer County, said that in nine operations of this kind he had been unable to recognize tuberculosis as the cause of the disease, and as he thought the irritation produced by a rubber drainage-tube had had a bad effect in some of his previous cases, he now preferred a very free incision and after-treatment calculated to keep a large sinus open for a long time.

Dr. JOHN CROXN, of Erie County, spoke particularly of the great importance of determining the condition of both kidneys, and cited a case in point in which a lady had suffered for many years with symptoms pointing to stone in the right kidney, and, although there was no evidence of disease of the other kidney, the post-mortem examination had shown that this too contained a large calculus. He hoped that in the future the cystoscope might prove a valuable aid to more perfect diagnosis.

Dr. THOMAS D. SREONG, of Chautauque County, related the history of a case of renal abscess which had come under his observation in which no tubercle bacilli had been found in the secretions, even when these were examined by competent observers. The patient had been operated upon in the Presbyterian Hospital, New York, and at present was recovering rapidly.

Dr. FERGUSON said that, although he did not think these cases were usually tubercular at the beginning, they were very liable to become so. In the great majority of cases of renal disease the process began at the lower portion of the genito-urinary tract and extended by continuity of tissue to the pelvis of the kidney. Anything that tended to increase the cystitis was apt to spread the disease upward through the ureters; hence he looked upon the use of the cystoscope and catheterism of the ureters as more hazardous than an exploratory incision.

Dr. JOHN W. S. GOULEY heartily indorsed this view, and added that not only was there but little risk attendant upon the exploratory operation, but if the diagnosis of renal disease was confirmed by operation, nephrotomy could be performed at once.

The Treatment of Epithelioma and the Canceroid Ulcers by Topical Applications.—In a paper with this title Dr. NELSON J. NORTH, of Kings County, favored the use of a concentrated solution of lactic acid, which he applied by rubbing it into the ulcers with sufficient force to break up the crusts. It should be particularly noted that lactic acid was not a caustic and did not produce an eschar which simply covered up the disease; it seemed to penetrate the abnormal cells and destroy their vitality. When applied to abnormal growths, lactic acid appeared to be at first absorbed by them, whereas it had very little effect on normal tissue. When it was applied to a carcinoma, the growth soon assumed a brownish appearance and became shrunken, and at the same time a process of osmosis seemed to be going on, for there was soon a discharge of a brownish liquid. Several cases of carcinoma of the uterus were reported in which this agent had been used to greater or less advantage. It would seem to have a sphere of usefulness in the treatment of "inoperable" cases.

(To be continued.)

NEW YORK NEUROLOGICAL SOCIETY.

Meeting of October 3, 1893.

The President, Dr. M. ALLEN STARR, in the Chair.

A Memorial of the late Professor Charcot was read by the PRESIDENT. The author gave a brief sketch of Charcot's life, and reviewed the work of the great neurologist. Professor Jean Marie Charcot was born in Paris on the 29th of November, 1825. He was the son of a wagon-maker, a man of such limited means that he was not able to give all his children an education. Jean Marie received his early education at the Lycée St. Louis, at that time the best academy in Paris. After his preliminary education was completed there, the choice of the medical profession was made, not without some hesitation, for the young man's inclination was for the life of an artist, and it was possibly the lack of means which finally determined him to take up medicine. After passing through the medical school and serving as an interne in the Salpêtrière—an almshouse for old women, then almost unknown, but subsequently to become famous as the seat of his wonderful activity—he took his doctorate degree in 1853. For the next three years he served as chief of the medical clinic in the Medical School, supporting himself meantime by giving private lessons. He was then appointed physician to the Central Bureau of Paris, on a moderate salary. In 1860, after passing a rigid competitive examination, he became entitled to a hospital appointment, and two years later he was able to select the service at his old hospital, the Salpêtrière. He found a large number of old people collected together in this poorhouse, many of them suffering from chronic incurable diseases. He had the opportunity of watching the progress of disease, both acute and chronic, in old age, and, most important of all, he had unlimited pathological material to complete his clinical observations. It is to this latter fact that he owed the beginning of his reputation, for at that time pathology was just beginning to reveal the true reasons for disease. By the careful study of his cases, by his power to seize upon salient features which gave points for distinction, by his persistent following of cases from the ward to the autopsy room, and by the exhaustive study of the material collected there, he began to reach conclusions and to arrive at facts which were veritable discoveries in the medical world. The articles written by him between 1860 and 1870, each of which added a distinct fact, observation, or conclusion to the sum of medical science, soon began to attract attention, and the young physician found his rounds beginning to be attended by students, who liked to watch his careful study of cases or see him demonstrate the lesions which he found. In 1866 a small room in the hospital was set aside for the purpose of instruction, and he began to hold clinics and to lecture. The lectures were soon crowded by graduates in medicine, and the next year he was invited to give an open course of lectures at the *École pratique* of the Medical School. Here he had an opportunity to cultivate the power of teaching, and soon showed that wonderful facility of clear, direct statement and power of graphic illustration which afterward made his lectures the most attractive in the world. His first open course had for its subject cerebral hæmorrhage and softening; in subsequent lectures he discussed the clinical and pathological differences between paralysis agitans and multiple sclerosis; the arthropathies, which have since been known as Charcot's joint disease, etc. Thus within four years he had risen from the position of an unknown teacher to the position of one of the best lecturers in the Paris school.

In the year 1870 all female epileptics and hysterics who were not insane were transferred to the Salpêtrière. This afforded Charcot new material for study, and from 1872 the study

of hysteria in its multiform manifestations became one of his duties. The same year he was appointed professor of pathological anatomy in the Faculty of Medicine in Paris, the highest prize in the French medical world. In 1882 a professorship of nervous diseases was founded in the Medical School, and Charcot received the appointment, with the establishment of a public clinic at the Salpêtrière. From that time to the present year his annual courses of lectures have been attended by students of medicine from every land, and it may be truly said that few men of eminence at present living and working in neurology have not drawn inspiration from his model clinics.

Charcot's collected works will fill fifteen large volumes. He was also instrumental in founding a number of medical journals. His three volumes of lectures, published from 1872 to 1880, have had an immense sale. Public recognition of Charcot's abilities and eminence was not wanting. He had been president of all the chief medical societies in Paris, and was a corresponding member of numerous societies abroad, among them the New York Academy of Medicine and the New York Neurological Society. He was made a member of the Institute of France in 1883, and Commander of the Legion of Honor in 1892.

Charcot's investigations in hypnotism have attracted much attention, both from the profession and from the laity. It is difficult for any one to enter upon the study of this subject, or to pursue it with any degree of thoroughness, without exposing himself to adverse criticism and remark. It is difficult to estimate the true value of this department of Charcot's labor, but it can not be denied that all through the years which he devoted to this study his mind has been imbued with the purest scientific motives, and that facts, not theories, were his aim.

Another criticism which has been offered is that in his scientific zeal he neglected therapeutics; that his interest in patients ceased with the diagnosis. Those who make these statements must surely forget that our best methods of treating functional and hysterical nervous diseases—namely, the electrical and hydrotherapeutic methods—were successively developed and successfully employed by Charcot.

Charcot was a man of great dignity, of calm, even temper, of slow thought and utterance, but of much reserve power. In appearance like Napoleon, and in manner reserved and observant, he was not the type of man to be popular. With patients suffering from trifling affections he showed no sympathy, probably no interest. With patients whose diseases were severe or obscure or of a rare type he was kind, attentive, and interested, and was ready to spend valuable time in most careful investigation.

His relation to his pupils was one of mutual interest and affection. He was never familiar with them, yet he always respected and sought their opinions, was never autocratic in the direction of their work, and was always the subject of their devoted admiration and respect. His family life was a delightful one. He was married early in life to a lady of considerable wealth, who was enthusiastic in his work and by whose aid many scientific undertakings otherwise impossible were carried through. He had two children, one a boy, whom it was his fond desire to see succeeding him as a physician, and who gives promise of being worthy of the name.

Charcot, like every man of eminence, had his enemies, critics in science, rivals in medicine; yet, after all their criticism is exhausted, we must admit that he remains the greatest French physician since Trousseau, and the greatest ornament of the medical profession of the present age.

Dr. E. C. SEGUIN gave a few personal reminiscences of Professor Charcot. He referred to the generosity of the great physician in placing at the disposal of his students his abundant material and the use of his laboratories, and in allowing them to receive the full credit for their labors, instead of appropriat-

ing it to himself. Many of Charcot's pupils—Bourneville, Bouchard, and others—had been helped by him in every possible way to attain honorable positions. In disposition he was quite different from the popular idea of the Frenchman. He was not quick, or hasty, or mercurial. Every thought was carefully matured, and he collected his material for a long time before reaching or publishing his conclusions. He was averse to theorizing. He was a close analyst and a devoted follower of the induction method in reaching conclusions. Primarily, Charcot was a pathologist, and his reputation would always rest on his achievements in this field of medicine. His work in hypnotism, by which he was greatly fascinated in his later years, can only be regarded as a mere fragment—a digression which in the future would count as nothing.

Generalized Paresis ending in Complete Recovery.—

Dr. E. C. SEGUIN gave the history of a case as follows: The patient was a boy, aged thirteen years, who was brought to the speaker in October, 1886, for an opinion as to the nature and prognosis of a singular condition of increasing muscular weakness which had come on during the preceding eighteen months. The boy's family history was fairly good. His mother was of a nervous temperament and for a few months had been addicted to the chloral habit. Out of six children, only one other, a sister, had had a nervous trouble—namely, a mild chorea extending over several years. There was no trace of muscular disease, atrophic or dystrophic, in the family. The patient's history previous to the onset of this disease was negative. At the age of six years he had had a severe attack of albuminuria, which had left no traces. In April, 1886, he had what seemed to be a mild attack of articular rheumatism. He was a very active and daring boy, and had had numerous falls, none of which, however, were followed by serious symptoms. There was a history of masturbation, carried on for several years. There was no history or evidence of metallic intoxication, and at no time was there any indication of hysteria. The only positive causative element in the case was the self-abuse. This practice, the boy stated, he had given up in the spring of 1885, when he himself had noticed that he had slight difficulty in articulating his words. Five months subsequent to this the boy's symptoms were first brought to his father's attention by the fact that he twice fell out of the saddle, and by his suddenly dropping the oars in a boat and acting as if paralyzed for a few minutes. Even before that, it was recalled, he had become rather awkward in buttoning his clothes and in using the knife and fork, and after he had read aloud for a few minutes his articulation had become thick. Very gradually he had lost his energetic ways and become awkward in everything; his attitude had changed so that he stooped, the head hanging down and the abdomen protruding. His facial muscles had lost much of their expression, and his laugh was constrained and unnatural. All these symptoms had developed and progressed very slowly during the years 1885 and 1886. The boy was subject to "sudden collapses," as his father called them, characterized by a sudden loss of control over many muscles, resulting in falls or in dropping objects from the hand. These last-named symptoms suggested *petit mal*, but this affection was excluded after careful observation. The symptoms were entirely of a motor order; no numbness, no anesthesia, no neuralgia, no psychotropic symptoms. All his organic functions were normally performed; nutrition was good. The eyes were normal. The legs were apparently strong, and the boy could rise from the dorsal recumbent posture on a flat couch and also from a squatting posture, but these acts were done feebly, slowly, and with great effort. The spine was not tender and presented no deviation, except an antero-posterior one. Local paresis of the muscles was demonstrable only in the extensor group of the

right forearm. No muscles showed atrophy or hypertrophy. The knee-jerk was normal. There were no sensory symptoms, except a sense of fatigue in the muscles of the lips and tongue, as well as those of the forearm, on exertion. On electrical examination, the reaction of the nerves and muscles to both currents was normal. The sexual organs showed no visible signs of masturbation. The grasp on the dynamometer was: Right hand, 11; left hand, 16.

These were the facts of main importance elicited at the first examination, in October, 1886. The boy remained under his care from that time on for about two years, during which period he decidedly improved in motor power and skill, and his height increased by six inches. The treatment from the first, in the absence of any possible pathological diagnosis, consisted in the systematic, long-continued administration of tonics—such as bichloride of mercury, phosphorus, arsenic, and strychnine. At the same time a mild faradaic current was applied systematically every day. Also, from the first, a cold sponge bath was ordered on rising or at bedtime, followed by a thorough dry rubbing and manipulation of all the muscles. Another part of the treatment consisted in gentle gymnastic movements of the hands, arms, trunk, and legs.

The case was lost sight of by Dr. Seguin from the close of the year 1888 until September, 1893, when, on inquiry, he received a letter from the boy's father stating that his son was now in the junior class at college, and that he stood well in his class and excelled in wrestling and other athletic sports. The treatment advised by Dr. Seguin had been faithfully carried out for nearly three years longer by the father, and had been followed by a gradual but continued improvement in the boy's condition. His weight at the present time was one hundred and sixty-six pounds. The circumference of his chest was: Expiration, thirty-three inches; full inspiration, thirty-nine inches. The circumference of his waist was thirty-one inches; that of his mid-thigh, twenty-two inches; that of his biceps, thirteen inches. His endurance was good, and he was able to raise from the ground an iron rail weighing six hundred pounds. His grasp on the dynamometer at present was: Right hand, 73; left hand, 53. This, Dr. Seguin said, was the strongest grasp he had ever met with.

Dr. B. SACS said that while he had been listening to the first part of Dr. Seguin's paper—before it told of the boy's remarkable recovery—the case had reminded him of a primary muscular dystrophy of the facial-scapular-humeral type, with perhaps some extension into the lower extremities. Such a case had recently come under his observation, with many symptoms very similar to those narrated by Dr. Seguin. In cases of progressive primary dystrophy, particularly in pseudo-hypertrophic conditions, he had seen marked temporary improvement following treatment, although he had never observed a complete cure. Again, in Dr. Seguin's case there might possibly have been some nuclear trouble, with a mingling of symptoms pointing to the spinal cord or the medulla oblongata. If the case was one of primary muscular dystrophy, the question arose whether the cure would be a lasting one. He had seen a number of cases with a condition of pseudo-hypertrophy in which the muscular tissue first enlarged and then rapidly atrophied.

Dr. GEORGE W. JACOBY suggested that Dr. Seguin's case might have been one of polymyositis ending in complete recovery, and followed by a secondary hypertrophy of the muscles which now existed.

Dr. J. F. TERRIBERRY stated that it was against the laws of pathology to assume that an inflammatory process in the muscular tissue was followed by hypertrophy of the muscle, with increased power.

Dr. E. D. FISHER said that when we took into consideration

the fact that the boy had grown six inches taller while he had been under Dr. Seguin's care, the lesion had probably not been a spinal one.

Dr. SEGUIN stated that the suggestion made by Dr. Sachs with reference to the possibility of curing a case of muscular dystrophy in its early stage was an interesting one; he was not prepared, however, to advance the case as an instance of that disease. Neither did it resemble a case of myositis. There had been no pain; there had been a general weakness, which had sometimes been so pronounced that the boy had been unable to hold objects in his hands, or would lose all control over his muscles and fall to the ground.

Book Notices.

The Art of Preserving Health. Outlines of Practical Hygiene adapted to American Conditions. By C. GILMAN CURRIER, M. D., Visiting Physician to the New York City Hospitals, etc. New York: E. B. Treat, 1893. Pp. v-468.

The author of this volume is already known to the profession as an earnest and careful investigator by his published papers on the self-purification of flowing water, on filters, and on other hygienic topics. He has prepared this work as a practical one that contains the results of the most recent investigations, with the particular purpose of adapting it especially to American conditions, a matter that will be appreciated by all who have occasion to refer to works on hygiene, the most important of which have heretofore been the publications of European authors written from the standpoint of the European environment.

The first section is devoted to the consideration of soil and climate. Soil is studied with reference to the conditions of sanitary residence and of the dissemination of micro-organisms through the earth or in dust. Under climate the author treats of air and its impurities, of the air moisture, of winds, of atmospheric density, and of the selection of climates in the treatment of disease.

The second section treats of the hygiene of clothing and bedding, properly preceding the subjects treated of in the third section, bathing and personal hygiene. A section is devoted to the various forms of physical exercise from a hygienic standpoint. As the author truly states, the prosperity of the commonwealth demands not only the best school training for children, but that the schools should in no wise impair the health of scholars or teachers, and he devotes a section to a consideration of the influence of schools on health.

The section on occupation indicates the conditions that affect the health of laborers unfavorably, and the remedies therefor.

In the section on lighting the author urges the superiority of electricity over all other means of lighting.

The section on buildings and streets treats of both private and public buildings, of residences, and of stores. The section on heating includes the choice of fuel, the construction of flues, and the methods of warming by stoves, hot air, hot water, and steam.

The section on ventilation is written so as to enable those occupying or building houses to determine and apply the best methods for securing a proper air supply.

The sections on food, on its preparation and adaptation, and on diet, give an excellent résumé of our knowledge of these topics.

The section on water and water supplies is an excellent one,

embodying as it does the author's wide observation and study of this subject.

In the section on sewers the author commends the utilization of sewage in fertilizing farms.

One of the best and most practical sections in the book is that on house drainage and plumbing, and it is so illustrated that any one can derive a clear idea of the difference between proper and poor plumbing.

Brief sections are devoted to the disposal of garbage and other solid refuse and to the disposal of the dead.

A clear description of the relation that bacteria bear to disease gives a better understanding of the facts discussed in the section on infectious diseases.

The section on disinfection and the restriction of communicable diseases discusses not only the disinfection of houses and rooms, but also the general principles of quarantine.

The book is admirably printed, the illustrations have been carefully selected, and we think the work has a field of usefulness before it.

Abnormal Man, being Essays on Education and Crime and related Subjects, with Digests of Literature and a Bibliography. By ARTHUR MACDONALD, Specialist of the Bureau of Education. Washington: Bureau of Education, Circular of Information No. 4, 1893. Pp. 445.

A BRIEF reference to this work needs no apology. It costs the country a large amount in life and work and money and wasted resources to care for the dependent and defective classes. The physicians of the country, if they knew how and would, could influence legislation in the right direction. That we are so helpless and uninfluential is due to our wasted opportunities and neglect of any literature outside the bread-and-butter question. When every subject of public health and happiness is represented in the doctor's library, the doctor's thought, and the doctor's conversation, the doctor will be respected and paid proportionately for his services and his advice will be followed by legislatures.

Here is a little book that every earnest, honest, and thinking physician should have in his library and read. The title shows the scope of the book. The author divides abnormal men into three classes—the criminal class, the insane class, and the class of geniuses and reformers. The treatment is clear and fundamental. Two hundred pages are devoted to a most valuable bibliography, which will be of the greatest assistance to the studious and careful readers. The whole book is so interesting that, once begun, it must be finished before another volume can command the reader's attention. It may be obtained from Mr. W. T. Harris, Commission of the Bureau of Education, Washington.

Heath's Practical Anatomy: a Manual of Dissections. Eighth Edition. Edited by WILLIAM ANDERSON, F. R. C. S., Surgeon and Lecturer on Anatomy at St. Thomas's Hospital, etc. With Three Hundred and Twenty-nine Engravings on Wood. Philadelphia: P. Blakiston, Son, & Co., 1893. Pp. xviii-744. [Price, \$5.]

The editor has assumed quite a task in preparing a new edition of this standard work, as he has made an extensive revision in order to bring it to a level with current teaching. One hundred and fifty pages of new matter have been added, a large portion of it being on the subject of topographical anatomy. A number of new illustrations have been substituted for others regarded as superfluous; in each instance in which an illustration has been taken from some other anatomical work due credit is given.

The editor has fulfilled his task in a careful and thorough manner, and this work is quite abreast with the text-books of the day and fully deserving of the commendation we have bestowed on former editions.

Nursery Problems. Edited by Dr. LEROY M. YALE. New York and Philadelphia: The Contemporary Publishing Company, 1893.

THE editor states that this little volume is made up of contributions to the columns of *Babyhood*. That magazine found that the replies to the inquiries addressed to the medical editor by anxious mothers proved to be such a popular feature that it was thought a selected collection might prove useful to a large circle of new readers. All young mothers will find much interesting information in the volume, and probably answers to many of the questions regarding their infants' welfare that vex them.

BOOKS, ETC., RECEIVED.

Anatomy, Descriptive and Surgical. By Henry Gray, F. R. S., Fellow of the Royal College of Surgeons, Lecturer on Anatomy at St. George's Hospital Medical School. The Drawings by H. V. Carter, M. D., late Demonstrator of Anatomy at St. George's Hospital. With Additional Drawings in Later Editions. A New American from the Thirteenth English Edition. Edited by T. Pickering Pick, Surgeon to and Lecturer on Surgery at St. George's Hospital. Philadelphia: Lea Brothers & Co., 1893. Pp. 24-33 to 1129.

A Text-book of Ophthalmology. By William F. Norris, A. M., M. D., Professor of Ophthalmology in the University of Pennsylvania, and Charles A. Olover, A. M., M. D., one of the Surgeons to the Wills Eye Hospital, Philadelphia. Illustrated with Five Colored Plates and Three Hundred and Fifty-seven Woodcuts. Philadelphia: Lea Brothers & Co., 1893. Pp. vii-19 to 641.

The Theory and Practice of Medicine. Prepared for Students and Practitioners. By James T. Whittaker, A. M., M. D., Professor of the Theory and Practice of Medicine in the Medical College of Ohio, etc. With a Chromo-lithographic Plate and Three Hundred Engravings. New York: William Wood & Co., 1893. Pp. xvii-3 to 821.

Nursery Problems. Edited by Dr. Leroy M. Yale. New York and Philadelphia: The Contemporary Publishing Company, 1893. Pp. 5 to 274.

Three Introductory Lectures on the Science of Thought. By F. Max Müller. With an Appendix which contains a Correspondence on Thought without Words, between F. Max Müller and Francis Galton, the Duke of Argyll, George J. Romanes, and Others. Chicago: The Open Court Publishing Company, 1893. Pp. vi-8 to 95. [Price, 25 cents.] [*The Religion of Science Library.*]

New Inventions, etc.

AN ADENOTOME FOR THE REMOVAL OF ADENOID GROWTHS IN THE VAULT OF THE PHARYNX.

By PETER J. GIBBONS, M. D.,
SYRACUSE, N. Y.

We are accustomed to remove hypertrophied pharyngeal tonsils or adenoids in the vault of the pharynx by means of forceps, curettes, snare écraseurs, or electrodes. But these methods I have found in my experience much inferior to removal by the adenotome here presented.

The apparatus was made by E. B. Meyrowitz, 104 East Twenty-third Street, New York. It consists of a broad, flat steel plate, with an oval opening in the distal extremity sufficiently large to receive the adenoid. To this is attached a knife, secured by lateral grooves, and so adjusted that in pushing the knife forward across the fenestra it will amputate as much of the adenoid as projects through the opening.

The handle is similar in construction to Bosworth's porta-castique for the pharyngeal vault, and can be readily taken apart. As will be seen, the shape favors an easy introduction behind the palate and to the base of the growth. Should the palate be retracted by reflex irritation, it would only embrace the tube of the instrument without in any degree hampering the manipulation. I sometimes find it convenient to use a palate retractor when introducing the instrument.

The manipulative technique is as follows:

With mouth well open, the handle is pressed upon the lower

teeth. The distal extremity is elevated and pushed backward with considerable vigor, thus working the ring of the instrument well down to the base of the gland, when, by a quick contraction of the fingers of the right hand, the peculiar mechanism of the instrument is brought into play and the adenoid cut through.

There is but trivial hæmorrhage, but little pain or retching, and the whole manipulation is accomplished very easily, simply, and speedily. The operation by this method, except in the case of young children, has rarely required an anæsthetic. As an aid to manipulation, we should always make use of cocaine, to thoroughly contract the blood-vessels and open up the nasal cavity, through which we can generally succeed in keeping the distal end of the instrument under ocular inspection.

324 WARREN STREET.

Miscellany.

Ovulation and Menstruation.—In the *Proceedings of the Royal Society*, No. 326, there is an abstract of a paper by Mr. Walter Heape, Balfour Student at the University of Cambridge, giving an account of his investigation of the phenomena of menstruation in *Semnopithecus entellus*.

The phenomena attending menstruation are grouped into four periods, and these are subdivided into eight stages: A. Period of rest. Stage I. The resting stage. B. Period of growth. Stage II. The growth of stroma. Stage III. The growth of vessels. C. Period of degeneration. Stage IV. The breaking down of vessels. Stage V. The formation of lacunæ. Stage VI. The rupture of lacunæ. Stage VII. The formation of the menstrual clot. D. Period of recuperation. Stage VIII. The recuperation stage.

The body of the uterus, says Mr. Heape, consists of an internal mucosa and external muscle layers. The mucosa is composed of uterine and glandular epithelium, blood-vessels, a few radial muscles, and stroma. The stroma has the appearance of embryonic mesoderm, the internuclear protoplasm is drawn out into very delicate processes, forming a continuous network, there is no intercellular substance to be seen, and a few long radial fibrils are present during the resting stage only. It is a very primitive tissue.

The author then describes the phenomena as follows:

Period A, Stage I.—The uterine epithelium is a single row of cubical cells; its outer edge is sharply defined in section, but the protoplasm of the base of the cells is continuous with the

protoplasmic processes of the stroma. The glandular epithelial cells are columnar; they rest on a basement membrane, but have no sheath. Round nuclei are imbedded in the protoplasmic network of the stroma, which is evenly disposed for one third of the depth of the mucosa, while below that a few radially arranged fibrils occur. The blood-vessels are small and fairly numerous.

Period B, Stage II.—An increase in the number of the nuclei of the stroma by amitotic division and probably by fragmentation causes swelling and increase of density in the upper third of the mucosa—hyperplasia. Owing to pressure, the nuclei become fusiform. An enlargement of vessels takes place. No decidual cells are formed. *Stage III.*—The mucosa is further swollen. The epithelium is stretched and becomes thinner. Hyperplasia of the vessels directly below the epithelium takes place and they are congested. The size of many of the nuclei of the stroma is reduced.

Period C, Stage IV.—Hypertrophy of the uterine epithelium of the stroma and of the walls of the vessels appears all over the mucosa, followed by degeneration in the superficial region, where the dilated, congested capillaries break down, the blood contained therein being extravasated among the stroma. The degeneration is probably amyloid or hyaline, not fatty degeneration. A considerable increase in the number of the leucocytes in the superficial vessels takes place. There is no migration of leucocytes and no diapedesis of red blood-corpuscles, but where vessels are ruptured a few leucocytes are swept out, together with red blood-corpuscles, into the surrounding tissue; many leucocytes, however, remain attached to the remnants of the walls of the broken-down vessels. *Stage V.*—The extravasated blood now collects into lacunæ, which are first formed within the stroma, but gradually extend superficially, displace the intervening stroma elements, and lie directly in contact with the epithelium. The vessels in the deeper mucosa remain intact; there is no trace of diapedesis and no red blood-corpuscles or leucocytes in the stroma in this region. *Stage VI.*—The lacunæ increase in size. The uterine epithelium and superficial stroma shrivel up and exhibit signs of degeneration. The epithelium ruptures and the blood contained in the lacunæ is poured into the uterine cavity. *Stage VII.*—Denudation follows. All the uterine epithelium, a portion of the glands, and in some places a whole gland, and a depth of about one third of the layer of the stroma is cast away, together with ruptured vessels, red blood-corpuscles, and leucocytes. Of these substances the menstrual clot is formed. This is a severe, devastating, periodic action, which is very remarkable. A ragged surface is left behind, and the remaining stroma contains, at or near the surface, masses of extravasated blood. In the deeper parts of the mucosa there is no further change.

Period D, Stage VIII.—The recuperation consists of the reformation of the epithelium, partly from the torn edges of the glands and partly by means of the transformation of stroma elements into flat epithelium; of the formation of new capillaries in the superficial region out of the stroma cells which surround the intercellular spaces in which the extravasated blood lies, and in the return of this reclaimed blood to the circulatory system; of the return of the vessels in the deeper mucosa to their normal size and consistence, and of the return of the stroma to the condition of rest (*Stage I*). The new epithelium, at first flattened, becomes cubical, and new glands are formed from folds of this epithelium. The numerous leucocytes left with the extravasated blood are returned to the circulatory system with the latter; they do not migrate, they do not form new tissue *in situ* or pus on the wounded surface.

Ovulation.—Out of the ovaries of forty-two specimens of menstruating *Semnopithecus entellus*, only two were found in

which recent discharged follicles were seen. Such a result appears to the author sufficient to warrant these statements: 1. Ovulation does not necessarily occur during each menstrual period, and 2. Menstruation is not brought about by ovulation.

The two corpora lutea seen, he says, occurred in specimens of *Stage III* and *Stage IV*; during these stages the first great increase of the blood supply to the mucosa takes place, and it therefore appears possible that the increased supply of blood to the generative organs during the early stages of menstruation may possibly induce ovulation when a sufficiently ripe ovum is present in the ovaries; there is direct proof, however, that an ovum is not dehiscid at each menstrual period.

Recent observations, says Mr. Heape, show that periods of growth and degeneration occur in the mucosa of the bitch when rutting, but denudation is not described. There is good reason to believe, he adds, that the period of growth is invariably present in the mucosa of rutting animals, and, as ovulation and rut are stated to be coincident, it appears highly probable that the period of growth during menstruation represents the preparation of the mucosa for the reception and retention of an ovum, while the degeneration period represents the result of failure to fertilize the ovum or failure of ovulation.

He ventures to express the belief that the function of menstruation may be thus expressed, but he fails to find any evidence of the origin of menstruation.

Electro-therapeutical Appliances.—At the recent meeting of the American Electro-therapeutical Association various committees reported as follows:

On Standard Coils.—The chairman of this committee, Dr. William James Morton, of New York, said that the subject was so large, and each month was bringing so many new facts, that it seemed premature to make a report as to what should constitute a standard coil. On motion, the committee was continued.

On Standard Meters.—Dr. Margaret A. Cleaves, of New York, read a report of this committee. The report stated that a good meter should possess a clear, legible scale of long range, and should be so constructed that it could be easily read by the operator while at work; that, although in itself a slant was not disadvantageous, it was undesirable because of the possibility of its heating and thereby changing its resistance; that the instrument should indicate in all positions, and was preferable when constructed to indicate with the current passing in either direction; that it should be very portable; and, lastly, that it should not easily get out of order. Instruments of the galvanometer type were considered to be inaccurate on account of the magnetic influence exerted by surrounding objects. Then followed a detailed description of the nine meters which had been submitted to the committee for examination, and the tests to which these instruments had been subjected. The report concluded with the statement that, in the opinion of the committee, the two meters which most nearly fulfilled the requirements were the Weston and the Kennelly meters, and the association was urged to adopt a standard meter at once. The report called for a long and earnest discussion as to the advisability of adopting a standard meter at present. Some of the members were of the opinion that one of the meters specially recommended by the committee had not been sufficiently long before the profession to enable many of those present to pass intelligently upon its advantages or disadvantages, and they therefore deprecated hasty action. Others thought it was impossible to combine in any one meter all the points a meter should possess in order to render it a thoroughly reliable instrument for all kinds of clinical work; and they consequently favored the adoption of two types of standard meters. It was also sug-

gested that to avoid unnecessary discrimination the association should adopt a type of meter as a standard rather than any one particular instrument. The report of the committee was finally accepted and the committee continued.

On Static Machines.—Dr. Morton reported that in order to pursue their investigations systematically a number of questions had been sent out in a circular letter, but no responses had been received. The committee made the following recommendation: That electro-static machines adapted to medical practice should not have fewer than four revolving plates, and that the diameter of these plates should not be less than twenty-six inches. The report of the committee was accepted and the committee continued.

On Constant Current Generators and Controllers.—Dr. W. J. Herdman, of Ann Arbor, read a carefully prepared report on this subject in which he considered in detail the work accomplished by the various batteries which had been submitted to him for examination. No secondary batteries had been submitted, and mention of one or two batteries which had only been very recently sent in was omitted for lack of time to make the necessary tests. On motion, the report was accepted and the committee continued.

On Electrodes.—Dr. A. Laphorn Smith, of Montreal, read a report of the committee. The committee expressed the opinion that the best ground work for all electrodes was copper-wire gauze, and that the connection was best made by copper wire soldered the whole length of the gauze and terminating in a binding post—that known as No. 632 (?)—which was largely used by telephone companies throughout the world. Clay was considered the best covering, as it was the only substance which could be rendered moist enough to conduct properly without at the same time soiling the patient's clothing. It should be half an inch thick and of the consistence of putty. Before each application it could readily be cleaned by washing its surface with soapsuds. The back of the electrode was insulated with common table oilcloth. The committee recommended three sizes of dispersing electrodes—viz., each having a uniform length of a foot, and the width three, six, and nine inches respectively. It was desirable that these sizes should be given in the metric system. For active electrodes to be used with the positive pole the committee naturally selected platinum as the best, its one objection being its first cost. Where the applications were to be made to the surface of the body or to the interior of a cavity like the uterus, carbon was equally good, and for such purposes carbon beads could be threaded on platinum wire. Zinc was also a useful material for intra-uterine galvano-cauterization. It should be connected with the rheophore by means of the standard binding post already mentioned. It was recommended that the conducting cords employed in electro-therapeutical work should be of the standard sizes and lengths used by the Bell Telephone Company. For negative intra-uterine application a Simpson sound made a useful electrode, and its size should be stated according to the French scale. Where the surface of the electrode was necessarily very irregular, its area should be determined by ascertaining how much water it would displace. It would be well for manufacturers to stamp all electrodes with two numbers—one giving the French scale and the other the displacement of water or the surface of the electrode. The committee recommended that a standard insulating material be adopted, and that the standard screw should be No. 240 of the American gauge. All electrodes should be washed with soapsuds after each application and boiled for five minutes before being used again.

Dr. Morton supplemented this report by presenting certain electrodes which he had devised, and which had proved useful in his practice. The first was a rubber covering for dispersing

electrodes. It was an elastic rubber cap which would slip over the various-sized electrodes, and which formed a pocket around the electrode, thus catching the water which would otherwise leak out on the patient's clothing. The second instrument was a new cataphoric electrode. With the usual form of this electrode it had been found impossible to apply the desired quantity of the medicated solution to the electrode without increasing the thickness of the blotting paper to such an extent that it interfered with and sometimes wholly prevented cataphoresis; for it was essential that the distance between metallic conduction and electrolytic conduction should be reduced to a minimum. To obviate this defect Dr. Morton had an electrode made in the form of a hollow box of hard rubber, the bottom of the box being formed by a piece of block tin perforated with numerous small holes. The box was filled with the desired quantity of the medicated solution, which passed through the small openings in the tin bottom and was fed to a thin piece of blotting paper on its lower surface. In this way any quantity of the solution might be employed without interfering in the slightest degree with the cataphoric action. The third instrument exhibited was an Apostoli intra uterine electrode insulated at the tip and at the cervical portion. In conclusion, the speaker referred to the advantages of punk as a covering for electrodes, and said his patients invariably found it the most agreeable covering of any employed. It had the great advantage of remaining moist for a long time.

Dr. G. Betton Massey, of Philadelphia, said that two years before he had devised an electrode made of a spiral of platinum wire inclosing a second spiral, the object of this construction being to facilitate rendering the instrument aseptic. A flat coil of No. 20 wire was, in his opinion, a much better basis for an electrode than gauze. If the French scale was employed, he thought it should indicate the diameter and not the circumference of the instrument.

Dr. Franklin H. Martin, of Chicago, called attention to the fact that he had been the first one to invent and exhibit a spiral electrode. His instrument had been first brought to the notice of the profession in 1887.

Dr. J. B. Greene, of Indiana, preferred the English to the French scale. The best material he had ever used for an electrode was moistened wood pulp; it was an excellent conductor, and so cheap that it could be thrown away after use. In his opinion, it would be impracticable to fix upon standard sizes for electrodes.

A communication was read from Dr. Lucy Hall Brown, of Brooklyn, in which she recommended a special electrode made of perforated brass plate covered with punk and connected to the rheophore by a peculiar spring clamp which she had devised.

The New York Academy of Medicine.—The special order for the meeting of Thursday evening, the 19th inst., was a paper by Dr. Andrew F. Currier, entitled *Myoma Uteri and its Treatment*.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 25th inst., Dr. N. T. Roberts is to read a paper on *Adenoids in Young Infants*.

At the next meeting of the Section in Obstetrics and Gynecology, on Thursday evening, the 26th inst., Dr. Edward P. Davis, of Philadelphia, is to read a paper on *The Toxemia of Pregnancy*.

At the next meeting of the Section in Public Health, Legal Medicine, and Medical and Vital Statistics [would that its title were curtailed!], on Monday evening, the 30th inst., Mr. Savage is to read a paper entitled *Dispensaries Historically and Locally Considered*.

Original Communications.

OBSERVATIONS ON POTT'S DISEASE,

WITH REFERENCE TO THE
PRINCIPLES OF TREATMENT AND THEIR APPLICATION.*

By ROYAL WHITMAN, M. D., M. R. C. S.,

LECTURER ON ORTHOPÆDIC SURGERY AT THE NEW YORK POLYCLINIC;
ASSISTANT SURGEON TO OUT PATIENTS,
HOSPITAL FOR THE RUPTURED AND CRIPPLED.

THE principles which govern the treatment of Pott's disease are somewhat as follows: It is tuberculous in character; therefore the general condition of the patient must be sustained by the constitutional and therapeutic measures that are indicated in other manifestations of tuberculous disease. It is a local affection of the bones and joints of the spine, accompanied by symptoms of pain and deformity that may be relieved or prevented by restraint of motion, protection from injury, and removal of superincumbent weight.

The treatment under which the general health is maintained, by which a proper attitude of the entire body is assured, which relieves pain and prevents deformity, is effective; when these conditions are not fulfilled, treatment is ineffective.

The successful treatment of Pott's disease depends upon (1) a knowledge of the functions and relations of the different portions of the spine, in order that one may interpret the early symptoms of disease, because a diagnosis can and must be made before the stage of bone deformity if the best result is to be attained.

2. A knowledge of the deformities and complications of disease peculiar to the region affected, in order that one may foresee and guard against them, for the final deformities of Pott's disease differ very materially with the region of the spine involved.

3. An apprehension of the nature of deformity and of the conditions that favor or retard its progress.

4. An appreciation of the duration and extent of disease and deformity, of the quality of the patient and the nature of his environment, in order that treatment may be applied intelligently or that a necessary compromise may be made between what is best and what is possible. The treatment of the patient in distinction to the treatment of his deformity is one of the more common and difficult problems, because patients are not often seen in the early stages of disease. The popular idea of Pott's disease is that it causes a hump, that the diagnosis is made because of the hump, and that the treatment consists in the application of a brace or plaster jacket without regard to the extent or position of the hump or to the symptoms or complications of disease. Consequently patients are brought for treatment in all stages of deformity or suffering, it may be from symptoms or complications that may call for special treatment, either because they directly influence the

course of the affection or indirectly increase the tendency to deformity.

In one, the constitutional depression of the tuberculous disease is out of proportion to its local manifestation; in another, great deformity has been acquired with practically no effect on the general condition. The complication of abscess may from its position endanger life in one instance, while in others it may increase the tendency to deformity, or interfere with effective support, or remain for a time and disappear without symptoms or consequences. The treatment which may be most effective in childhood, when the danger of deformity is greater than the danger to life, may not be applied to the adult, for whom the relative danger of the constitutional and local disease is reversed.

The object of treatment is the prevention of deformity; not only because the effect of treatment is estimated by the degree of ultimate deformity rather than by the survival of the patient, but because deformity itself, after complete recovery from constitutional and local disease, by its distortion and compression of vital organs, is a constant source of weakness and danger.

To apprehend the nature of deformity, its causes and final results, one must bear in mind the fact that the spine is a flexible column, which, balanced under the influence of the force of gravity, is constantly changing its shape to accommodate itself to the different attitudes and movements of the body.

If by disease the function of one portion is interfered with, another part must accommodate itself to the change.

If one section is deformed or thrown out of its true relation to the weight line, another part must change in the opposite direction.

These compensatory changes, though bearing a necessary relation to the original cause, may, in the growing child, become exaggerated and independent deformities, or permanent distortions may be acquired which originally were merely symptomatic of disease. The deformities of Pott's disease may thus be divided into two groups, the essential and the non-essential. The essential deformities are those caused by destruction of bone and loss of growth—two factors modified to a great extent by early diagnosis and efficient treatment.

Pott's disease is a destructive process which affects the bodies of the vertebræ, the weight-supporting portion of the spinal column. As the effect of weakness and loss of support, the superior section of the spine inclines forward, bringing more weight, and thus the influence of attrition, to bear on the diseased area. The more rapid the destructive process, the more often abscess complicates the condition; this abscess may dissect its way down the spine, infecting other vertebræ in its progress. It is apparent, then, that while the disease causes deformity, the deformity may increase the disease.

The non-essential and more distinctly preventable deformities are those which depend upon the symptoms or complications of the disease; one of these is muscular spasm. In disease of the cervical region, for example, the head may be drawn into a wryneck position, which, if

* Read by title at the seventh annual meeting of the American Orthopædic Association.

allowed to persist, becomes a permanent deformity, for contracted tissues do not grow and the bones of the spine quickly accommodate themselves to the changed condition of weight and function; or abscess which involves muscles and fascia may induce a faulty attitude. This is well illustrated in disease of the lower region of the spine, in

FIG. 1.

FIG. 2.

which the compensatory lordosis or overerectness of the body is one of the favorable factors in prognosis (Figs. 1 and 2). When, however, psoas abscess causes flexion of the thighs, the erect posture is impossible (Fig. 3); thus the habitual attitude becomes most unfavorable and, if it is allowed to persist, permanent and unnecessary deformity may result (Fig. 4).

Simple weakness is another element of deformity. When one sees a child suffering from dorsal disease walking about in the squatting attitude of weakness, supporting the body by

the hands on the knees, it is very evident that treatment is ineffective, because a proper attitude is not maintained.

After the cure of the primary disease, the resulting

FIG. 3.

FIG. 4.

deformity and the general weakness favor secondary curvatures of the spine, just as weakness and faulty attitudes may cause postural curvatures without the influence of local disease.

When the spine is distorted, the thorax must, in a certain degree, participate in the change; but the exaggerated pigeon-

breast deformity of dorsal disease can be prevented by efficient treatment.

The natural tendency of Pott's disease is to cause a right-angled deformity at the point of weakness. The opportunity for deformity is greatest when the middle of the spine is diseased, because the column is broken in the center. The opportunity for deformity is small when either extremity is affected, because the deformed portion is insignificant compared to that which remains intact. It is evident, then, that it is not the mere angular projection, the direct and essential effect of the local disease, which is of importance, but that the true measure of deformity is the effect of the disease or deformity on the spine as a whole. (Contrast Figs. 6 and 7.)

Each region of the spine, because of its position, functions, or relations, presents certain peculiarities which influence prognosis and treatment. Disease of the occipitotaxoid section, the region of true joint motion, is not infrequently a primary affection of the synovial membrane; consequently, more acute in symptoms and rapid in progress.

Disease of this region is more dangerous because of the proximity of the vital centers and because of the possibility of sudden displacement and pressure on the cord.

It is not infrequently complicated by abscess, which, unable to find an outlet, dissects its way about the contiguous vertebrae, or forms a tumor in the throat which may interfere with breathing and swallowing.

On the other hand, because of the acute symptoms, an early diagnosis is usually made, and, under favorable circumstances, the course of the disease is short and the result favorable.

The most disastrous deformity of this region—one not infrequently seen in untreated cases—is caused by the falling forward of the head so that the chin becomes fixed upon the sternum. The indications for treatment are to prevent ultimate displacement of the head by fixing it in the line of the normal spine and at a right angle to it.

The prognosis in disease of the middle of the neck is favorable from all standpoints, because the special movements of the head are unaffected and because the opportunity for final deformity is slight. Children are often brought for treatment in whom the right-angled deformity, concealed by the occiput, has never been discovered by the parents or physician. Disease of this region is often accompanied by painful contraction of muscles and distortion of the head, often complicated by enlarged or suppurating glands or sinuses. The indications for treatment are therefore the removal of the superincumbent weight of the head and relief of muscular spasm by active extension.

In disease of the upper and middle dorsal region the prognosis is particularly unfavorable as regards deformity. The disease is not, as a rule, discovered at an early stage, because motion in this region is slight, and the symptoms are therefore not pronounced.

The normal posterior curvature of the spine is markedly exaggerated by slight deformity, while the compensatory lordosis tends to increase rather than to limit the kyphosis. The course of the disease is long, and the tendency to increasing deformity remains after complete cure of the local disease. The direct effect of deformity in compressing and distorting the thoracic viscera, and thus causing permanent weakness, is often very apparent (Fig. 5). A most serious and not infrequent complication of disease in this region is paralysis from secondary implication of the spinal cord. The indications for treatment are to combat all deformities, primary or secondary; to prevent the forward inclination of the head and neck; to restrain unnecessary movements of the arms; to draw the shoulders backward; to prevent the secondary deformity of the chest and the compensatory lordosis.

The prognosis in disease of the middle of the spine is favorable if the patient is seen in the early stage, because

the mechanical conditions are such as to make apparatus effective in relieving symptoms and preventing deformity.

If neglected, disease of this region produces the typical humpback (Fig. 6), the dwarfed stature, the square shoulders, the sunken head, and the distorted back and chest.

At a lower point the attitude symptomatic of disease tends to prevent great deformity, but in a large proportion of cases abscess and psoas contraction change this attitude to an unfavorable one. The indications for treatment are to restrain the awkward attitude of overerectness and to guard against the effect of psoas contraction. If this con-

FIG. 5.

FIG. 6.

traction is on one side only, the proper attitude of the spine may be maintained by providing the patient with a high shoe on the unaffected leg and crutches. If the contraction is of both sides, the patient should not be allowed to go about, but the irritation must be relieved by complete rest, or the abscess treated directly.

In the two regions of the spine, the upper and lower, in which abscess most often makes its appearance, radical operation is most often indicated; in the first, because of its position; in the second, because of its size and deforming influence. In both these regions it is sometimes possible to reach and remove the source of suppuration. Except as an imperative necessity, the radical treatment of abscesses should not be undertaken unless the proper conditions for treatment can be assured, unless the source of pus can be reached, and unless there is a fair prospect of avoiding a suppurating sinus, which is often a source of danger and discomfort to the patient or interferes with effective support.

Abscess is a symptom of disease of which the importance is estimated by its effects. It may be prevented, and its extent and course may be modified by proper treatment of the cause of which it is a symptom. The aspiration of abscesses, with the injection of antituberculous remedies, is the treatment by preference. It is often effective and always harmless.

In the treatment of Pott's disease, rest and fixation in the horizontal position fulfill all the mechanical conditions: superincumbent weight is removed; the function of the diseased spine ceases; jars, injury, and overfatigue are impossible.

On the other hand, this treatment is incomplete in itself, because it must be supplemented by some form of mechanical support when the erect posture is again assumed.

It necessitates confinement and lack of exercise, the constitutional stimulation very essential in the treatment of tuberculous disease. The duration of Pott's disease is estimated in months and years; thus the moral effect of help-

lessness and confinement for such a period must be considered. In general, this treatment is a last resort, or is a temporary measure indicated for the relief of pain or threatened complications. In certain cases it is the treatment by preference; as in infancy and early childhood, because the spine is in great part cartilaginous, the effect of disease in checking the growth and in the rapid production of deformity is very marked.

Young children submit very readily to a treatment that relieves them of discomfort and pain—that is, in fact, a simple prolongation of the helplessness of infancy.

The treatment is usually indicated for a longer or shorter time under the following conditions: In disease of the upper cervical region, because the head may be fixed, the danger of abscess lessened, dislocation and deformity prevented, pain relieved, and the progress of the disease checked before joint motion is greatly impaired. In disease of the upper dorsal region in young children, because progressive deformity is difficult to control, and a proper attitude difficult to maintain by apparatus. In disease of the middle thoracic region, in which the grunting respiration and the faulty attitude—the evidences of pain and weakness—show that treatment is ineffective. In disease of the lumbar region, in which the complication of psoas contraction makes the erect posture difficult or impossible.

This treatment is always indicated when pain is not relieved by other means; in the acute phases of disease, shown by pain, fever, and rapidly increasing deformity; in the complication of paralysis; or for the radical treatment of abscess.

To be effective, the rest treatment must always include fixation and often extension, and the apparatus must be entirely independent for its effectiveness of the bed on which it is placed. The most simple and useful appliance is, I believe, the frame first recommended by Bradford. The frame is made of light steel bars or gas pipe, a little longer and as wide as the child's body. This frame is covered by canvas, which is made smooth and rigid by straps or corset lacings on the under surface; between the two layers a thin hair mattress may be inserted if desirable.

For older children it is well to apply the canvas cover in three sections, the narrow middle sheet to be removed for the use of the bed pan. This is unnecessary when diapers are used, the middle portion being protected by rubber sheeting.

Two or more sets of covers (sheets) are necessary, in order that the apparatus may be perfectly clean, for an unclean child is always neglected.

The patient must be fixed to the frame; the child who can raise the head or turn the body is uncomfortable and unhappy because he can not sit up, but when motion is impossible he quickly accustoms himself to restraint. To fix the patient, the shoulders and the head are the two points of advantage. If the shoulders are fixed, he can not turn over; and if the head is held, he will not attempt to sit up. The patient is usually attached to the frame in the following manner: A broad swathe surrounds the body and the frame, and straps attached to the frame are passed

over the shoulders and through the axillæ, while a band across the chest prevents displacement.

Traction is indicated in cervical disease, and may be applied with advantage in disease of the upper dorsal region, with the aim of reducing deformity. Traction is easily accomplished by the ordinary halter attached to a slightly flexible steel upright, screwed to the brace after the manner of the jury mast. The amount of traction is regulated by raising the head of the frame; this allows the child to look about and is often as effective as the weight and pulley. Pillows beneath the head are not often indicated; in fact, it is sometimes necessary to loosen the upper part of the canvas so that the occiput may fall back, and to place a pad beneath the dorsal region if effective traction is to be applied in disease of that region; by this means in young children it is sometimes possible to reduce what is apparently deformity of bone. In the treatment of cervical disease, particularly in those cases in which the displaced bone projects forward, it may be necessary to place a pillow beneath the head as a temporary support.

Psoas contraction, even if complicated with abscess, often disappears under the influence of rest. If, however, this position has long been maintained, it may be necessary to apply traction to the legs, as in the treatment of the deformities of hip disease.

The rest treatment is not often indicated in cases of great deformity, or in half-grown children or adults, except to meet certain indications, some of which have been mentioned; but it may be applied, and almost always with advantage, in the treatment of any region of the spine in infancy or early childhood. The patients may be taken into the open air daily, pain is relieved, the condition of the patient improves, while growth is often very rapid. Strong objection to the treatment is often made by the parents, but, once applied, its effects are so apparent that it may be continued without protest until other indications call for change.

If the essential conditions can be fulfilled by treatment which does not confine the patient to the bed or house—in other words, does not make an invalid of him—this is the treatment by preference.

The principle of support in the erect posture is this: If the body is inclined forward, the weight or pressure is supported by the bodies of the vertebrae. When the body is inclined backward or held in the upright position, more weight is supported by the articular processes. This is what is meant by relief from superincumbent weight as effected by a spinal support; in addition, it fixes the spine and protects it from the injury of motion.

If the point of disease is above the thoracic section, superincumbent weight may be actually lifted; the body support then acts primarily as a base of support for the attachment which fixes or lifts the head.

The two types of appliance used are the plaster jacket and the spinal brace. Each of these has advocates who seem to base their conclusions on the failures of the one rather than on a personal comparison of the merits of the two; the desirability of interchanging the two methods of

treatment is not often considered in the discussion or writings on this subject.

The jacket is brought into disrepute because it can be so easily and is so often applied by those who have a blind faith in its efficacy as a specific for humpback; the brace, because of a lack of knowledge of the principles of its construction or application.

The jacket is in fact a simple circular plaster bandage, which, like any other plaster bandage, depends for its efficiency on the size and irregularities of the surface to which it is applied and on the distance to which it extends on either side of the point to be fixed; for example, a plaster bandage applied to the knee of an adult may be an effective support, yet is useless on the leg of an infant. So the plaster jacket may be admirably effective when applied under proper conditions, and absolutely ineffective under others.

The plaster jacket provides a general support for the trunk as a whole; solid at the sides, front, and back; less accurately adjusted than the brace at the seat of disease. The abdomen is supported and counterpressure applied to the chest without uncomfortable tension. The jacket is most effective as a support in disease of the middle of the back, less effective at a lower point, because the unyielding plaster does not allow the accurate adjustment to the pelvis that may be afforded by the brace. The brace, which is more effective in the lower region, is also more effective in the middle and upper dorsal region, because, by an appliance that I have elsewhere described (*Transactions of the Orthopædic Association*, vols. iv and v, and *Philadelphia Medical News*, November 19, 1892), backward traction may be applied to the shoulders, the leverage of the brace increased, and greater fixation assured by restraint of unnecessary forward-reaching movements of the arms, which act directly on the weakened spine to increase the deformity.

The jacket is admirably effective as a support in disease of the middle region in adults. It is a better support than the brace in cases of marked deformity and in cases of lateral distortion of the spine. When the neck region is involved the choice between the brace and jacket is more often one of relative comfort than of other importance. The jury mast is usually associated with the plaster jacket, but may equally well be used with the brace. In disease of the occipito-axoid region greater fixation of the head than is afforded by the jury mast is usually indicated; while in the painful distortion of the neck, associated it may be with suppurating sinuses or inflamed glands, the active traction afforded by the jury mast and halter is more comfortable and effective than the simple fixation of the metallic head supports. A disadvantage of the jury mast is that it is a very noticeable and rather offensive support. This is a matter of some importance, because head or chin supports are oftener indicated in disease of the dorsal region than is usually taught, not for the relief of pain, but to check the tendency to slowly increasing deformity. In such cases an inoffensive chin rest may be used when the jury mast would not be tolerated. One may conclude, then, that while the brace and its attachments has a wider range of application,

under certain conditions the jacket is more comfortable and more effective.

The faults of the jacket, as it is often applied, are that it is made too short below to support the abdomen, but allows it to bulge out beneath—thus it fails in support and predisposes to hernia; that it is not carried high enough to cover the chest and assure efficient counterpressure; that jury masts are not applied when they are indicated, are not strong enough to support the weight of the head, and that traction is not properly applied.

FIG. 7.

Most of the spinal braces sold in shops are useless; others are not properly fitted or the aprons are too short or made of yielding material which allows uneven and uncomfortable tension. While either method, properly carried out, may meet all the ordinary indications in treatment, there are occasions when one is distinctly preferable to the other, or when the appliances may be interchanged with advantage.

The object of mechanical treatment is to free the spine from the influence of local deformity (Fig. 7) and from the deforming influence of the symptoms and complications of disease; to distribute the compensation which is necessary and to limit that which is unnecessary.

The test of an appliance is its efficiency in meeting these indications; the test of treatment is its effect upon the patient.

CATARACT EXTRACTION WITH THE IRIS RETRACTOR.*

By FRANCIS VALK, M.D.,

INSTRUCTOR IN DISEASES OF THE EYE,
NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL, ETC.

SINCE the early part of 1887 I have performed the operation for the removal of cataract by a method somewhat different from that usually adopted.

This I have placed before the profession at the Post-graduate School, at the State society, and also at the meeting of the New York Academy of Medicine; but, owing to unforeseen circumstances, there has been no opportunity for my colleagues of New York city to criticise or to discuss the merits or demerits of the retraction of the iris and the removal of the lens *at the same time*. I have therefore asked the honor and the privilege of bringing this matter before the congress, that it may meet with a full and fair discussion.

I shall always highly appreciate the opinions and suggestions of those who entered this special branch of surgery before I attempted to step on the first round of the ladder of fame, as well as the remarks of those who are working side by side with me in trying to advance this noble art, even though our efforts may not meet with the approval of all. Still, we hope these are but steps forward, if I may

call them such, that they may some day fall into the hands of men who may so improve them as to produce far better results.

I do not propose to discuss the merits of the different methods for the removal of the sclerosed lens which intercepts the rays of light, nor the special features of an operation with or without an iridectomy, as the advantages of a round and normal pupil are well known and obvious. Nor yet do I believe there will ever be a day when the conscientious surgeon will adhere strictly to only one method of operation, but will always adopt that which he thinks best for the ultimate good of his patients.

Therefore it is my intention in this paper to suggest some thoughts and a method that have occurred to me in the course of my limited number of operations, and to explain the use and advantages of the simple little instrument, "the iris retractor," that I have used whenever possible during the past four years.

As regards the *time to operate*. I think this should be decided, when we find the cataractous lens sufficiently hardened to admit of its ready removal, without any reference to what the vision in the other eye may be. If our patients are willing to have an operation performed, even though the vision may be good in one eye, say $\frac{2}{8}$, then you are justified in taking the slight risk there may be of failure, for the benefit of the improved binocular field of vision. The blindness on one side renders our patients at a disadvantage, as some of my cases will show; at the same time we make a useless eye ready for practical vision when its fellow lens becomes opaque.

Preparation for the Operation.—We may do nothing as regards the ultimate success except so far as we may have the mind of our patients completely at rest. In the light of the present statistics, the chances of failure in a healthy eye, if a cataractous eye can be healthy, are very small, as you may readily see by the reports of cases lately published. So I do not in any way prepare my cases beforehand, and particularly avoid the use of atropine before the operation.

Operation.—At the time when I am ready for the operation I instill a sufficient quantity of a solution of cocaine (four per cent.) to render the cornea anæsthetic, but not to dilate the pupil. The patient is then placed on a steady table or bed with a good clear light on the eye, and the lids are opened with the speculum. The eye is then washed with a solution of boric acid, while my instruments are all placed in boiling water and then on a clean towel and covered until wanted.

Section.—This I consider the most important part of the operation, as upon a good section, I believe, depends the ultimate success. This should be in the same plane, except at the finish, as I shall describe. I wish to avoid the conjunctival flap, and by the perfect coaptation of the wound in the cornea we may avoid slow healing, septic infection, and prolapse or incarceration of the iris. I make the section either upward or downward according to the eye to be operated upon—as upward in the right eye, downward in the left, or, if the operator is ambidextrous, then both sections may be made upward, as I consider the

* Read before the Section in Ophthalmology of the First Pan-American Medical Congress.

upward section preferable. I prefer, in making my section, to cut always toward myself, for in so doing we produce a much smoother and clearer cut. I always make the puncture and counterpuncture wholly within the corneal tissue, through its transparent margin, about one millimetre from its periphery, and so that the cutting edge of the knife will just cover the pupillary edge of the iris on the side toward which I propose to make the section. If possible, I rapidly make the section of the cornea with three distinct cuts: first, carrying the point of the knife, as soon as the counterpuncture is made, upward and forward, cutting one side of the cornea; then the heel of the blade is drawn upward and backward, so cutting the opposite side; then, turning the knife on its long axis, the section is completed with the third cut by pushing the knife steadily forward until released. I think De Wecker, of Paris, first suggested this method, and I prefer it to all others. As I complete the section in the above manner, the knife comes out some distance from the scleral junction, leaving room for the iris to be tucked in when drawn back by the retractor.

At this time we may have prolapse of the iris; if so, it must be returned with the spatula if we wish to save the iris; but, if not, then it may be drawn out and cut off if we decide an iridectomy is best. Another complication that may occur at this stage, particularly in very old people, is the rupture of the capsule or the zone of Zinn with the presentation of the lens at the section; if so, it must be removed at once by pressure on the cornea. I am inclined to think that should there be any tendency to prolapse at this stage, it is better to perform an iridectomy at once, to prevent any future prolapse as the healing process proceeds. If no complications arise, I then proceed to open the capsule by a peripheral incision, passing the cystotome inward to the pupillary space, then under the iris, and sweep it around beneath the edge so as to cut the capsule in more than one third of its periphery on the same side that the section has been made.

My next step is the drawing back of the iris and the extraction of the lens. At this point I wish to say a few words in reference to my method of the retraction of the iris with the little instrument called the "iris retractor," which I now present, claiming that I first adopted and practiced this method. In the *Archives of Ophthalmology*, May, 1888, page 60, Dr. Herman Knapp states that before and since he read his first paper on this subject, he had drawn back the iris toward its periphery, where he found that membrane somewhat rigid, using the small wire loop; but he does not state that he held the iris *drawn back* until the lens was removed, so I infer that he simply drew it back to relieve its rigidity, or to break up any adhesions that may have formed between the iris and the anterior capsule.

Again, I find an article by Dr. Barton Pitts, of St. Joseph, Missouri, in the *Medical Record*, October, 1890, wherein he describes a method of operation by which he draws back the iris with the same wire loop which Dr. Knapp used, and held it there until the lens passed out by pressure on the cornea. In the same paper Dr. Pitts criti-

cises my retractor, when, according to his own admissions, he has never seen my instrument, nor does he even know its construction, but has simply followed out my ideas of drawing back the iris and holding it *tucked back* until the lens is removed. He does not give me the credit of having first adopted that procedure, though his ideas may be original with himself.

I will quote Dr. Pitts's words: "By Dr. Valk a distensible shield with two knobs is proposed. The method of its manipulation is to insert through the corneal wound, cover the surface of the iris, and, by the knobs holding in the pupil, retract the iris upward as far as necessary and slide the lens over the front surface of the shield. Dr. Valk reports good success with it. I have not tried it, nor am I familiar with its pattern except from description. I should think, however, it objectionable on the score of occupying considerable space, already too limited. Its insertion, moreover, I think awkward, and, in the event of sudden movement of the eye under operation, its presence in the anterior chamber especially dangerous. . . . To overcome the resistance of the iris and frequent rigidity of the pupil, I have for two years resorted to the same instrument recently mentioned by Dr. Knapp as used by him—that is, a fine wire loop attached to a delicate handle. This instrument, which can be easily and thoroughly sterilized, I insinuate through the corneal wound into the pupillary space and retract the iris into the superior triangular space, and by a gentle pressure backward and upward of a strabismus hook, applied against the lower edge of the cornea, I have little difficulty in the delivery of the lens and without material injury to the iris, and in no instance accompanied by loss of a single drop of vitreous or followed by septic infection of the eye." I have quoted his remarks thus fully that you may note the different methods, and also if this little instrument is at all objectionable because it occupies too much space, or is especially dangerous in any sudden movements. I have never found it so, and in reality this retractor of mine does not take up any more room than the wire loop; nor is it *awkward* in any sense, as it can be easily removed from the eye by simply tipping up the ends of the blades, thus instantly releasing the iris, and at once removed if necessary.

It seems to me that the construction of this little instrument is extremely simple, having only two small smooth knobs on the ends of a forceps with crossed action, and the size of the ordinary iris forceps. These little knobs, standing at right angles to the axis of the ends of the blades and pointing downward, simply hold the iris tucked back in the superior triangular space until the lens passes into the corneal wound, when the iris is at once and easily released.

When we consider the ease with which the lens passes out and the slight pressure required on the cornea—so much less than in the simple extraction universally adopted at the present day—I feel justified in claiming some merit and originality for this little retractor.

The eye being now ready for the extraction of the lens, it is grasped by the fixation forceps, directly opposite the section, and held steady by a careful assistant.

I now take the retractor in the left hand, and, with the blades closed and the set screw so arranged that the blades will open to about the diameter of the pupil, I insinuate the ends through the section to the pupillary space. The blades are now opened by pressure and the iris drawn back and tucked beneath the edge of the lower corneal section. Holding it steady in that position, a slight pressure is made on the opposite side of the cornea by a spoon or hook, causing the lens to rise up and easily pass out over the ends of the blades. As it does so, and as soon as the lens presents itself at the section, the retractor is pushed slightly inward, at once releasing the iris. The retractor is then generally removed with the lens lying in the concavity of the blades. As the lens clears away, we find the iris back in its position, not injured in any way, nor has it been exposed to the air, as may occur in simple extraction.

In case there should be any cortex remaining which I do not think will be absorbed or will interfere with the vision, I have reintroduced the retractor, and, drawing back the iris again, these masses are easily pressed out with the spoon. This completes the operation, and, the section being in perfect apposition, the speculum is removed, the eye gently closed, and the bandage applied.

After-treatment.—There seems to be as much diversity of opinion as regards the method of after-treatment of an operation at the present day as there is in the methods of operation, even so far as not to use any bandage or dressings of any kind. I note that Professor Knapp does not close the eye until about half an hour after the operation, in order to see if there is any tendency of prolapse. He only applies the cotton and isinglass slips, while Chisolm, of Baltimore, does not even apply any cotton; but as I have watched the healing process of my cases and noted the different conditions under which my patients have from necessity been placed, I am inclined to think that it is best to take a "happy medium" with a decided modification of the old strict method in use some years ago. Our first consideration must be the ultimate success of the operation, and next the daily comfort of our patients as the healing process proceeds. Bearing these two points in mind, it seems to me that there will be fewer movements of the eye and consequently less pressure on the sclera by the straight muscles if we close both eyes with a neat-fitting flannel bandage, with pads of absorbent cotton over the eyes. The slight restraint of a day or two in bed will not cause any distress, while the rest and quiet will assist in the rapid healing of the large corneal wound. I do not doubt but that those who use the modified dressings have as good success as can be wished for, though the above ideas seem to me the best that we may employ to complete the healing of our patients, according to the old motto, *Tuto, cito et jucunde*.

I remove the bandage from the eye not operated upon at the end of forty-eight hours, or on the second day, as I do not wish, nor do I see any need, to keep these old people in the dark any longer than is absolutely necessary.

In my last four cases I have tried to carry out my ideas of non-interference still further, as I sometimes think

that atropine may irritate an eye which has been operated upon for cataract, and lately I have not used this drug unless necessary—that is, when there were indications of commencing iritis; but I have changed the bandage every twenty-four hours, washing the lids carefully and gently with warm water, applying a little vaseline to the edges of the lids, and then replace the bandage.

Now I wish to make another suggestion in reference to that desire, which we perhaps all have, to look at the eye and to see the result of our work. Is it not better to leave the eye alone until all possible danger of complications has passed? Some of us have noted an opening of the wound with prolapse of the iris as late as the sixth day after the operation. Therefore I have decided to simply change the dressings every day for about ten days, unless there are some indications otherwise, and then open the eye in a darkened room, gradually accustoming it to light by the use of smoked glasses.

Professor P. D. Keyser, of Philadelphia, and Dr. W. Buss, of Bradford, Pa., have used my retractor in several cases and have reported to me good results, each being pleased with the easy exit of the lens and the rapid healing of the wound in the cornea.

In conclusion, I do not think the surgeon who considers the best interests of his patients and the various conditions that may arise during an operation for the removal of cataract will persistently adhere to any one method of operation. In my own cases I have been compelled to lay aside the retractor in four cases out of thirty-three. So the surgeon must adopt that method which to him at the time seems best for the ultimate success, either with or without an iridectomy; but we can adopt some method and endeavor to carry it out, unless we find it will endanger the final results.

Some of my cases have required a subsequent discission; but as each case of that kind requires special study and methods in itself, I will not make any particular reference to it, except so far as I consider Dr. Knapp's remarks as to the operation, delivered at Detroit, as the best, and giving the final results required.

In the following table I give the histories of twenty-nine cases in which the retractor was used, being private and clinical cases. In some of my dispensary patients I could not get the final tests, as they would disappear after the healing of the wound.

In all these cases I have used the *retractor*, though some of them have presented indications almost against its use; but the final results have seemed equal to those of any other method, while in four cases not reported I could not use the retractor and the final results were not as satisfactory, and in one case, where I performed an iridectomy, the end was total loss.

This method is perfectly safe and the retractor can, if necessary, be quickly and easily removed from the eye, while the objection once raised, that it is another instrument introduced into the eye, is not tenable, as this instrument is so easily sterilized, and, besides, I think there is less manipulation of the iris than in simple extraction, particularly if the iris is prolapsed at the exit of the lens.

26	F.	54	Julia B. F.	R.	"	Congenital, partially absorbed.	$\frac{20}{20}$ w. + $\frac{1}{2}$.	
27	F.	47	C. H. B.	R.	"	Senile.	$\frac{20}{20}$ w. 12 D.	
28	M.	58	F. R. H.	R.	"	"	$\frac{20}{20}$ w. 10 D. \bigcirc 4 D., ax. 180° .	To have discission.
29	F.	55	C. D.	L.	"	"	$\frac{20}{20}$ w. + $\frac{1}{2}$ \bigcirc + $\frac{1}{5}$ c., ax. 180° .	

Final results: $\frac{20}{20}$ - 1; 1; $\frac{20}{20}$; 2; $\frac{20}{20}$; 8; $\frac{20}{20}$; 5; $\frac{20}{20}$; 3; $\frac{20}{20}$; 4; shadows, 4; no result, 1; no test, 1.

I will close by stating that by this method I do not meet with any more accidents or risks, as loss of vitreous, etc., than usually occur by other methods, and I believe that with careful use the retractor, as I now present it and as I have used it for the past four years, will be of material service to the ophthalmic surgeon in the removal of a cataractous lens.

The instrument may be procured from E. B. Meyrowitz, of New York.

BUBOES AND THEIR TREATMENT.*

By J. GARLAND SHERRILL, M.D.,
LOUISVILLE, KY.

INASMUCH as this affection is met with very frequently, not only by the surgeon, but also by the general practitioner, I have decided to offer it for your consideration. Moreover, it is a subject upon which very little attention has been bestowed.†

The term bubo is derived from *βουβών*, the groin, and at first was used to represent a glandular tumor in the groin; at a later period the term included a glandular tumor in any locality. At present it is taken to mean an enlargement produced by a lymphadenitis in the groin. The superficial inguinal glands of the groin, numbering from eight to twelve, are divided into two groups. The superior group, which lies parallel to Poupart's ligament, receives the lymphatic vessels from the skin of the scrotum, penis (labia majora and minora in females), the

perineal and gluteal region, and the mucous membrane of the urethra. The inferior, which lies in the axis of the thigh near the saphenous opening, receives the vessels from the lower extremity and communicates with the superior by vessels running from above downward. This arrangement is such that venereal buboes are nearly always situated in the superior group, but occasionally the poison passes these to reach the lower group, and is of course then situated below Poupart's ligament. When a patient presents an inflammatory swelling in the groin the first thought is, Where is the sore? but although strongly probable that the trouble has a venereal origin, such is not necessarily the case, as a number of other causes may be at work in the production of a bubo. This affection may result from strains—violent muscular exercise, as lifting, mounting a horse, etc.—ingrowing toenail, injury to the foot, ulcer, direct traumatism, herpes, furuncles, and eczema, as well as from venereal disease. Therefore buboes may be classed as venereal and non-venereal. Venereal bubo may follow either gonorrhœa (with or without) chancreoid ulcer or syphilis.

They may also be classified, according to course—

1. Simple inflammatory.
2. Virulent.
3. Specific—where due to syphilitic infection.

Buboes are said to be rarely produced by gonorrhœa alone, but upon several occasions have I seen them complicating this affection with no syphilitic or chancreoid lesion, and very frequently a slight inflammation of these glands not followed by suppuration. A hypertrophied condition of these glands is a frequent result of repeated attacks of gonorrhœa. The most common cause of bubo is a chancreoid. About thirty-three per cent. of chancreoids

* Read before the Falls City Medical Society, April, 1892.

† Since this paper was read a number of articles have appeared which would appear to contradict this statement.

are followed by bubo, and half of these are simple, notwithstanding Ricord's law that chancreoid virus, if absorbed by a gland, produced virulent or self-inoculable bubo. The adenitis usually appears upon the same side as the original sore; occasionally it is on the opposite side. If sore in the median line, especially at the frenum, the enlargement occurs on both sides. In about thirty-one cases in a hundred the gland at the root of the penis is involved. The size of the chancreoid has nothing to do with the virulence of the resulting bubo. The retention of the discharge is, however, no unimportant element in the production of buboes, by concentrating the poison, as in phimosis. The bubo may appear at any time during the course of a chancreoid. A Hunterian true syphilitic sore is almost always followed by an infection of the lymphatic chain of the groin within two weeks; subsequently all the lymphatic glands are enlarged. This infection of all the lymphatic glands is characteristic of syphilis, as is the chronic course of the bubo. On this account it is called indolent. There has been considerable discussion as to whether a venereal bubo can occur without an initial sore. It is at present generally conceded that in every case a lesion is present, which may, however, be so small as to escape the notice of the patient.

Simple bubo is a simple inflammation of one or more glands in the groin, produced not, as was formerly supposed, by sympathy, but by the poison conveyed through the lymphatic vessels without affecting the vessels, or at most causing a very slight inflammation of their coats. The irritant, having come in contact with these glands, excites an increase of the blood supply. Cells are infiltrated into the spaces of the glands, and also in the periglandular tissue, the amount of this infiltration depending on the amount and character of the infectious material.

If only sufficient to excite a slight inflammation, as in simple bubo, the gland becomes only a little enlarged and tender, and will soon return to normal by the absorption of the inflammatory products. If, however, the irritant is more powerful, as after chancreoid, the distention becomes so great that the cells in the center are deprived of their blood supply and break down, forming a purulent focus which acts in turn as an irritant, and as a result the whole gland is destroyed and an abscess is the result. The wall of this pus cavity is formed by a very much thickened capsule, which becomes united superficially to the skin. The skin also becomes inflamed, and after a time, along with the abscess sac, becomes thinned, as a result of the pressure from within, and rupture of the abscess occurs, unless relieved by incision. The pus continues to discharge for quite a while, owing to the size of the opening, and finally after weeks, and perhaps months, the sac closes, leaving an indurated spot with a ragged, irregular cicatrix.

The virulent bubo follows a course similar to the simple, save that it develops more rapidly, and immediately assumes the ragged form of a chancreoid when evacuation takes place, the pus inoculating any abraded surface with which it comes in contact. It is also liable to attacks of phagedæna, which is not the case with the simple.

The syphilitic bubo differs from both of these in being

slow in development, with the same round-celled infiltration which is found in chancre. This, after an indefinite period of time, undergoes resolution, and very rarely does suppuration take place. Only in strumous patients, where the patient suffers from what has been called galloping syphilis, does suppuration take place.

Symptoms.—Simple bubo at first gives rise to a discomfort while walking, and a feeling of fullness in the groin. Examination at this time reveals a small, rounded, or oval swelling, which is movable under the skin and tender to the touch. These symptoms increase, and the tumor becomes more elongated and less movable; the skin over it becomes red, tense, and perhaps oedematous. Pain is a marked symptom at this time, and the patient is unable to move about. After from one to four or five weeks resolution may take place, leaving a chronic induration, or the skin will become thinned and shining when suppuration has taken place and the abscess bursts with a protracted cure. At first the virulent bubo takes this same course, but is developed more rapidly, and *always* ends in suppuration. The periglandular structure may suppurate, and, if so, will open first and discharge non-inoculable pus; later, when glandular abscess opens, will be inoculable.

The syphilitic bubo runs an essentially chronic course without pain, usually giving very little annoyance to the patient, except from its size, and finally undergoes resolution.

Diagnosis.—A virulent bubo can scarcely be told from a simple one before suppuration occurs. The rapidity of its course, self-inoculability, and the severity of the symptoms are the only guides. After rupture the ragged appearance assumed by the edges of the ulcer (abscess) will decide. The syphilitic bubo can be told by the history of a chancre in every instance, and by its chronic course and painless character. It is never self-inoculable.

Treatment.—As regards prophylaxis, little can be done to prevent syphilitic bubo, while the liability to its occurrence after gonorrhœa and chancreoid may be very much lessened by perfect quiet, avoidance of strong injections, with perfect cleanliness. Bumstead and Taylor maintain that cauterization of the chancreoid does not lessen the liability to bubo; but I think an early cauterization, with perfect cleanliness afterward, will be found to lessen the frequency of the glandular inflammation. I think most of the later writers will bear me out in this statement. All of the text-books advise an attempt at aborting the inflammation, and, failing in this, try to aid suppuration. The means proposed for this are both numerous and unreliable. Older authorities recommend painting with iodine; later ones think it harmful, and with good reason, as the inflammation is undoubtedly increased, as is the suffering of the patient in a direct ratio. Mercury preparations, lead and opium, aconite and belladonna, cold, heat, blisters, leeches, pressure, etc., have been proposed, most of which do very little if any good, and some of them positive harm. Better results can be obtained from heat or pressure with a spica bandage than from the other methods of abortion. Why should any attempt be made to abort a bubo when you are unable to distinguish a simple from a virulent inflammation until sup-

puration and rupture occur? A virulent bubo of necessity suppurates, and the simple bubo very often takes this course, and in the majority of cases it is a simple waste of time to attempt to abort the trouble. After suppuration has taken place, every one will agree that an incision is the proper procedure. Until quite recently surgeons have seemed afraid to make a free incision, opening the abscess by a puncture, and leaving the patient to suffer for a long time with a discharging sore. The usual treatment now in vogue after suppuration has taken place seems to be a free incision, followed by the use of the scoop to remove undestroyed parts of the gland. Dr. Herman Kimmel, as early as 1882, recommended the thorough removal of all the glands, healthy or unhealthy, thorough cleansing of the wound after the slight hemorrhage had been stopped, placing drains in the pockets if any were present, and closure of the wound by suture. He then applied pads of bichloride gauze, and retained them by a roller with firm pressure. This dressing he left undisturbed for a week.

The plan which I have used in my last dozen or more cases is by no means original, and was first brought to my notice by Dr. ApMorgan Vance, of this city. I think it possesses so many advantages over the other plans of treatment that it should become more generally adopted. Instead of wasting time trying to abort the inflammation, and after watching the case for two or three days, if the patient still suffers much pain and inconvenience, I resort to the immediate removal of all the inflamed glands. A free incision over the inflamed tissue down to the glandular structure will reveal the inflamed gland lying loosely in its capsule. Very little difficulty will be experienced in its removal. The hemorrhage should be controlled and the wound irrigated with hot water containing some antiseptic; if preferred, dried and sprinkled with iodoform; then packed with iodoform gauze and covered with a compress fixed by a spica. The dressing should be changed on the second day, and at longer intervals after that time. The advantages afforded by this method are—

1. A complete and rapid recovery—at the very longest, in two weeks.
2. Relief of the patient from a number of weeks' suffering and inconvenience, as it is possible for him to be out in three days, and the pain is instantly relieved.
3. The almost certain prevention of a virulent sore, and this of necessity excludes the possibility of the wound being attacked by phagedæna.
4. The absence of danger or difficulty in carrying out the treatment.
5. The relief to the surgeon from the well-worn phrase, "Doctor, I am no better." Hearing this every day or so for a number of weeks grows very tiresome.

The only objection that could possibly be offered to this plan of treatment is that it leaves its history in the scar. But what plan of treatment does not leave a scar? And I think very little stress can be laid upon a slight disfigurement in this locality. All I ask for the plan is a trial, and I am positive that, once used, no other plan will take its place.

558 SECOND STREET.

A CASE OF SARCOMA OF THE SOFT PALATE, ILLUSTRATING THE DEGENERATION OF A BENIGN (PAPILLOMA) INTO A MALIGNANT GROWTH. *REMOVAL OF THE SOFT PALATE. DEATH.**

By W. K. SIMPSON, M. D.

The possibility of the degeneration of benign into malignant growths is a matter of such intense interest that any data bearing on the subject should be brought to the surface and receive the consideration that its importance demands.

The thorough understanding of this possibility will serve to guard our prognosis in cases seemingly benign, and will guide us in determining to what extent operative procedures may be instituted. Although the subject of this degeneration has received exhaustive treatment quite recently at the hands of Dr. Felix Semon, especially as regards laryngeal neoplasms, and although the conclusions of his investigations are decidedly against the change taking place as often as was supposed, still, that there are unquestioned instances of this degeneration I think there can be no reasonable doubt. Dr. J. Solis-Cohen published one in the proceedings of this society for 1892 under the title of Adeno-sarcoma of the Larynx at the Site of a Papilloma removed Sixteen Years previously.

Without going into any research regarding the literature of the subject, I will simply offer the history of the following case, imperfect, possibly, in some of its details, but extremely convincing and instructive in others.

A further object in presenting this case is to preserve the sequel of its previous publication.

The case was first reported by Dr. G. M. Lefferts at the session of 1889 of this society under the title of Multiple Papillomata of the Velum, illustrated and published in the transactions of that year, a full report of which I herewith append.

"The differential diagnosis in cases so well marked and distinctive as these presents no difficulty. Microscopical signs alone will suffice for the recognition of their true nature. Although papillomata are the commonest variety of true neoplasms of the fauces, a growth the size of that shown in the present instance must be unusual.

"It occurred in a girl aged sixteen years, who only accidentally noticed its presence in her throat when it had attained one third the dimensions here shown. Thereafter it grew rapidly and in eight months' time resembled the drawing. Little or no inconvenience was caused, dysphasia never being present, and but slight interference with the timbre of the voice. After anesthesia of the parts by cocaine the multiple tumors that made up the mass were removed by scissors curved on the flat. The uvula was not involved and was left intact. A superficial stellar cicatrix now shows the former site of the sessile portion of the mass. There have been no signs of recurrence."

This report was made three months after operation.

Sixteen months after removal of the original tumor by Dr. Lefferts a reappearance of growths similar to the ones removed occurred, at which time Dr. Lefferts kindly placed the patient

* Read before the American Laryngological Association at its fifteenth annual congress.

in my care for treatment, at that time May 14, 1890. I found several distinct papillomatous masses of various sizes springing from different parts of the soft palate, principally about the free margin, one or two extending down on the left anterior palatine pillar. They were of grayish-red color, freely movable on more or less of a pedicle, and with every physical appearance peculiar to benign papillomata, and, as Dr. Lefferts remarked, absolutely identical with the previous ones he had removed. There was no other evidence of inflammatory changes or thickening of the soft palate, and the seat of the original growth was smooth and free from any attempt at recurrence. Believing, from their appearance and from the previously published record, that they were papillomata, I removed most of the growths by galvano-cautery knife.

From May 14, 1890, to July 26, 1890, I removed several of these growths which made their appearance from time to time, using at times lactic acid in the proportion of from fifty per cent. to full strength and the galvano-cautery, and although at times I removed nearly all of the soft palate, thinking I was completely clear of all morbid tissue, still the cavity left by removal would become most rapidly filled up by a return of the growths, the short space of a week sufficing at times to fill a very large excavation.

Coincidentally with the recurrence of these tumors I noticed during this space of ten weeks that the growths were losing their benign appearance and infiltration of the soft palate was taking place. Each recurrence became more dense, and by July 26th the soft palate presented one large inflexible indurated mass. By this time all resemblance to the original type of growth had disappeared, and it was very evident that it was becoming malignant in character, probably a sarcoma. A microscopic examination made at this time by Dr. George Thatcher, pathologist to the Presbyterian Hospital, revealed such to be the case. The patient complained of no pain whatever, but only a slight difficulty in swallowing and slight thickening of speech. There was no enlargement of the cervical glands. I decided that the most advantageous course to pursue was the removal of the whole soft palate from all its surroundings, and to that end I had the patient transferred to the Presbyterian Hospital, where, on August 2, 1890, Dr. Andrew J. McCosh removed the entire soft palate. The operation was done very carefully and skillfully by means of the knife and scissors, under cocaine, by spray and hypodermic injection of a four-per cent. solution. The operation was done with the patient in sitting posture and consumed about an hour and a half. One drachm (gr. ijss.) of the solution was used by the needle in addition to the spray, and not the slightest untoward symptom occurred, the patient exhibiting a most wonderful fortitude and aiding most materially by her intelligence. There was but slight hæmorrhage, which was easily controlled. After the removal in its entirety it was found to be almost one mass of very dense sarcomatous tissue with a slight adhesion (sarcomatous in nature) between the upper right posterior surface of the soft palate and the pharyngeal wall. This adhesion was thoroughly scraped. The patient made a good immediate recovery from the operation, and for a short time there was no return of the growth, but by October, 1890 (two months after removal), unmistakable signs of recurrence showed themselves, extending up the naso-pharynx, which precluded any idea of further operation. In October, 1890, the patient left the city and passed from under my observation. I learned, however, from the patient's family and attending physician that the growth extended very rapidly up in the naso-pharynx and down the pharynx, interfering with speech to the extent that she had to communicate by writing, and preventing deglutition, and she finally died of inanition April 26, 1891, two years and three months from

the first appearance of the apparently benign papilloma and eight months after the final operation.

In Conclusion.—There is possibly one link lacking in the complete chain of evidence in this case, and that is, I understand from Dr. Lefferts that the original tumor was not examined microscopically, but he expresses himself as being positive that there could be no doubt. His description and drawings certainly favor its being a papilloma, and when I saw the first recurrence I could not come to any other conclusion. That a microscopical examination is necessary for an absolute diagnosis I will not deny, but the microscope sometimes misleads or fails to absolutely confirm. Another point for consideration is the effect of the mode of removal of these growths. Though the cautery and lactic acid were effectual in removing them, I can not but think that the reaction from these agents is so great at times as to possibly favor a change to malignancy. That there would have been an extensive recurrence of the original growths there is not much doubt, and if the malignant degeneration could have been foreseen it doubtless would have been delayed by an early removal of the entire soft palate.

INDIRECT MASSAGE OF THE LENS FOR THE ARTIFICIAL RIPENING OF CATARACT.*

By EDWARD JACKSON, A. M., M. D.,

PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC;
SURGEON TO WILLS EYE HOSPITAL.

At the meeting of the American Medical Association in 1892, Dr. Joseph A. White, of Richmond, Va., reported to the Section in Ophthalmology a series of cases in which the ripening of immature cataract had been hastened by the method suggested by Dr. T. R. Pooley, of New York (*New York Medical Journal*, December 26, 1885); and in the *Archives of Ophthalmology*, vol. xxi, No. 4, he published a paper upon the subject.

Since hearing Dr. White's report I have tested the method in a series of cases in which it seemed indicated by the presence of clear, soft cortex in the lens, and, finding it in the main satisfactory, desire to call your further attention to it. The following are abstracts of my notes on the cases in which the method was employed:

CASE I.—R. C., a draughtsman, aged sixty-two years; always near-sighted; applied August 13, 1891, on account of recent increase in difficulty in seeing. Each lens presented a moderate nuclear haze with apparently normal vitreous and fundus. His correcting lenses and vision were: R. — 1.50 — 0.50 cyl., axis 180° = $\frac{1}{5}$; L. — 2.50 sph. = $\frac{1}{5}$.

He was fitted with these lenses and kept under observation. The nuclear opacity continued to increase, until before the operation for preliminary ripening vision with glasses had fallen to R. $\frac{1}{5}$, L. $\frac{2}{8}$.

On June 14, 1892, the anterior chamber was emptied with a paracentesis needle, and massage of the lens practiced through the cornea. No immediate effect on the lens was noticed. On the 15th there was considerable conjunctival hyperæmia and pericorneal injection. On June 21st there still remained some pericorneal injection and the opacity of the lens had much in-

* Read before the American Ophthalmological Society, July, 1893.

creased. Four days later all hyperæmia and irritability had subsided.

July 23d.—No fundus reflex could be obtained in any part of the dilated pupil. The iris cast no shadow, but there still appeared to be fragments of clear cortex near the anterior pole of the lens. He was told to wait until cooler weather for extraction; but meeting with an accident, which confined him to bed for some weeks, did not return until December. Simple extraction was done December 8th, the lens proving to be entirely opaque, above the average size, with a great deal of soft cortex, which, however, came cleanly away without difficulty. Healing was normal except for some adhesions of the iris to the upper lip of the corneal wound, and a high post-operative astigmatism, which diminished slowly.

March 13, 1893.—With the right eye he could count fingers at six feet; left, with + 8 sph. \odot + 4 cyl., axis 153° , vision = $\frac{1}{2}$ mostly.

CASE II.—T. G., an iron worker, aged fifty-one years, had noticed failing sight for eight years in the left eye, and in the right for two months prior to his appearance at the clinic.

September 27, 1892.—His vision was, R. $\frac{5}{8}$; L. $\frac{3}{8}$.

In the right lens there was opacity of the anterior and posterior cortex in the lower portions, with good view of the fundus above. In the left there was nuclear and extensive cortical opacity, most dense at the anterior and posterior poles, with good fundus reflex in the margin of the dilated pupil.

September 29th.—Paracentesis and indirect massage of the lens was done on the left eye. Immediately after the operation there was a faint gray reflex from the lens surface not previously present.

October 1st.—The eye was free from hyperæmia. There was slight increase in the lens opacity and the patient was permitted to leave the hospital and go home.

October 18th.—The opacity of the visible cortex was complete. The anterior chamber distinctly more shallow than in the other eye.

October 20th.—Lens extracted, proving to be large with much soft cortex, which came away completely. There was more than the average reaction following extraction and slight iritis. However, in two weeks the eye was almost free from hyperæmia; pupil free and circular.

December 6th.—Without needling the capsule his correcting lens and vision were: R. — 0.50 \odot + 1.75 cyl., axis 30° = $\frac{1}{2}$; L. + 8 \odot + 2.50 cyl., axis 170° = $\frac{1}{8}$.

CASE III.—W. S., aged fifty-two years, piano maker. Finds all glasses that he can get unsatisfactory.

February 4, 1892.—Vision, R. $\frac{5}{8}$; L. $\frac{1}{8}$. Right, high mixed astigmatism and cortical opacity of lens in lower temporal quadrant, which does not encroach on the undilated pupil. Left, high astigmatism, radiating and cloudy opacity in both the anterior and posterior cortex, with full fundus reflex through most parts of the lens. R. + 2.75 sph. \odot — 5 cyl., axis 180° = $\frac{1}{8}$; L. not improved.

He was seen from time to time, vision continuing to grow worse until December 24th. In the left eye he was then only able to count fingers at two feet. Paracentesis with indirect massage of the lens was practiced.

December 27th.—Counts fingers at eighteen inches. Slight pericorneal redness. No appreciable change in the lens.

December 31st.—Counts fingers at nine inches. Marked increase of lens opacity. Eye free from hyperæmia.

January 5, 1893.—Vision reduced to perception of moving objects. Anterior portions of the lens opaque. Lens removed by simple extraction. Posterior cortex still fairly clear. The healing was normal.

March 18th.—R. with + 12 sph. \odot + 0.75 cyl., axis 145° , vision = $\frac{1}{8}$ without secondary operation.

CASE IV.—Mrs. J. G. B., aged sixty-four years, had noticed failure of vision in right for one year and in left for three months before applying, January 14, 1893. She has been wearing concave spherical lens 4 D. Vision: R. counts fingers at twelve inches; L. $\frac{5}{8}$.

The right pupil was occupied by gray opacity tinged with faint red reflex. The upper portion of the lens seemed slightly hazy throughout, with more dense opacity near the anterior and posterior poles. The left eye presented opacity mainly in the posterior cortex of the lower outer third of the lens with one spicule in the anterior cortex.

January 26th.—Condition unchanged. Paracentesis and indirect massage done on the right eye. After the operation there was a faint gray film at the surface of the lens, and a slight pink or faint claret color to the whole aqueous humor, probably from slight hæmorrhage of the iris. Two days later the eye was quite free from hyperæmia and no trace of red reflex visible in the pupil. Simple extraction was done February 7th.

April 22d.—Without needling the capsule her correcting lenses and vision were: R. + 8 \odot + 0.75 cyl., axis 180° = $\frac{1}{2}$.

CASE V.—Mrs. H., aged thirty-three years, housework. Several years ago first noticed failing vision in the right eye, and for the past three years there has been similar failure of the left.

February 14, 1893.—The right eye presents diffused opacities of the lens, hiding the condition of the vitreous and all details of the fundus. Good fundus reflex in all directions. Left nuclear opacity of lens; fundus dimly seen, apparently normal, and normal vitreous. Vision: R. $\frac{5}{8}$; L. $\frac{3}{8}$, slightly improved by a — 0.50 D. sph.

April 6, 1893.—No change in the condition of the eyes under treatment. No improvement by glasses. Vision the same.

I did paracentesis and indirect massage on the right eye, taking special care to withdraw all aqueous and making more vigorous and prolonged massage than in any of the previous cases. At the close of the operation a slight film was noticed at the anterior surface of the lens.

April 8th.—Free from hyperæmia. The film before noticed has disappeared.

April 20th.—The lens remains precisely as before the operation. Vision unchanged. Made small incision in the anterior capsule with Bowman's stout needle.

May 23d.—There is still but a very small strictly localized opacity at the seat of puncture of the anterior capsule. Vision, $\frac{5}{8}$. Extracted a comparatively clear lens, which came away completely through a rather small incision.

June 15th.—The eye free from irritability. Some wrinkling and opacity of capsule with diffused and localized opacities of the vitreous. The capsule was freely incised, and July 12th, with + 9 \odot + 4 cyl., axis 10° , vision = $\frac{1}{2}$ partly.

CASE VI.—Lewis C., aged fifteen years, peddler. Two years ago had pain and inflammation in the right eye attended with failure of vision.

February 18, 1893.—Drooping of the right upper lid, excluding that eye from vision. Chronic conjunctivitis with thickening of the lids. Pupils equal, normal. Right eye slightly divergent. Diffused cloudy opacity, apparently near the anterior surface of the lens. Good fundus reflex in all directions. Vision equal to $\frac{5}{8}$. Left eye, hyperopia: 1 D.; media clear; vision, $\frac{1}{2}$.

March 18th.—No change in the right eye under treatment. Paracentesis and indirect massage of the lens, decidedly more

vigorous than I commonly employed, produced no perceptible change in the opacity.

June 24th.—Vision, $\frac{3}{80}$. Appearance of lens as when first seen.

CASE VII.—A. O. S., aged sixty years, compositor. Had noticed failure of vision in the right eye for three years, progressive.

April 22d.—Vision, R., counts fingers at four inches. L. $\frac{1}{80}$.

By dilatation of the right pupil, vision was increased to counting fingers at four feet. The whole lens was found hazy, but with perceptible red reflex showing through it in all portions, there being no dense localized opacities. L., vision normal.

April 25th.—Paracentesis and indirect massage were done on the right eye.

April 27th.—Vision unchanged, red reflex still distinct in all portions of the pupil, eye free from hyperæmia.

May 2d.—With fully dilated pupil, counts fingers at ten inches. There is still faint red reflex visible through certain parts of the lens; marked increase of opacity in the anterior cortex.

May 9th.—No red reflex. Vision reduced to light perception.

May 23d.—Lens, mainly soft cortex, portions of the posterior layers of which were comparatively clear, was removed by simple extraction. Recovery normal.

July 7th.—11 D. sph. \ominus + 3 cyl., axis 190°. Vision = $\frac{1}{2}$.

As regards the efficiency of the operation, it will be noticed that the cases here reported may be divided into two groups. Case V, aged thirty-three years, and Case VI, aged fifteen years, showed no change whatever in the condition of the lens opacity as a result of the operation. As regards these cases, it was quite ineffective. The other five cases, ranging from fifty-one to sixty-four years of age, all show rapid and satisfactory increase in the lens opacity as the result of operation.

The practical efficiency of the operation is seen by the fact that in all five cases the vision was speedily reduced to light perception, all red reflex abolished, the extraction was complete, and good vision was obtained without any secondary operation.

I believe that in nearly all cases after extraction there comes a time when the vision is markedly improved by division of the capsule, and that in the majority a secondary operation will give better vision from the start. The point of importance here is that in these cases the indications for division of the capsule were no greater than after the extraction of cataracts that have attained complete maturity without surgical interference.

In the matter of efficiency my experience indicates that indirect massage is decidedly superior to Förster's operation. It would appear, however, that it is efficient only in senile cataract—that is, only when the opaque lens contains a rather large, firm nucleus.

In support of this, my colleague, Dr. A. D. Hall, informs me that he has twice tried the operation for juvenile cataract with precisely the same experience, not the slightest effect being produced on the lens opacity.

As regards the safety of the operation, I can only say that the ocular and physical conditions in these cases were not more favorable than in the average of cataract cases,

yet they exhibited little more reaction than would be expected from the puncture of the cornea and the withdrawal of the aqueous humor. There has not been any sign of iritis, or a single posterior synechia; and the eyes all did well at the time of extraction and subsequently.

There was nothing like dislocation of the lens produced in any case, nor do I think such an accident could ever result from the manipulations necessary to effect the desired maturity of the cataract, except in eyes in which it is liable to occur spontaneously, or from any slight blow or jar of the head.

As to the need for such an operation, it seems to me very important, both for physical, mental, and economic reasons, that cataract should be removed as soon as it has reached visual maturity—that is, so soon as it greatly interferes with the independence and comfort of the patient; if its removal is at all likely to restore the patient to comfort and independence. If, then, it is best that a cataract should also be surgically mature, that the lens should be completely opaque before its removal is undertaken, the need for such an operation as this seems clear and imperative. But whether it is really best to always secure complete opacity of the lens before proceeding to extract it may still be questioned. My own experience in extracting immature cataracts which still have some soft cortex, without a previous ripening operation, has been less satisfactory than that detailed with reference to this operation; yet, on the whole, it has been by no means unsatisfactory, and something might be said in favor of extracting immature cataracts as against their previous maturation.

The Method of Operating.—After the full dilatation of the pupil and the free instillation of cocaine, the anterior chamber is tapped with a paracentesis needle or broad needle, the incision being kept open by the point of the needle until the aqueous has been completely withdrawn with some little pressure of the fingers through the lids upon the globe. I use the fingers for fixation without a speculum. Then a tortoise-shell spatula is pressed upon the cornea within the area of the pupil and rubbed around in a circle, and then in radiating lines, stroking from the center toward the periphery of the cornea. During this latter manipulation the margin of the pupil will be seen to retreat before the spatula, so that a large part of the anterior surface of the lens can be acted on without pressure upon the iris. The manipulation is continued a minute and a half to two minutes and a half.

The after-treatment consists of closing the eye for a few hours, and the subsequent instillation of a mydriatic, until the eye is free from hyperæmia. The preliminary instillation of cocaine is repeated three or four times, using it more freely than I would for cataract extraction, with the idea of rendering the cornea more flexible.

To summarize my conclusions with reference to this method of ripening cataract:

It seems more certainly efficient than Förster's.

It is almost entirely free from danger.

It is probably a better means of avoiding prolonged practical blindness than the extraction of the immature cataract.

A CASE OF SUPERNUMERARY NIPPLES,

WITH REMARKS UPON THE SUBJECT
AND ITS LITERATURE.*

By ALBERT PICK, M. D.,

MANCHESTER, N. H.

Mrs. N. N., aged thirty-one years, an American, of very good physical development. She has given birth to two healthy children and has had one miscarriage.

She presents a supernumerary nipple on the lateral aspect of each mamma, about midway between the normally situated nipples and axillæ. The accessory nipple of the left gland is quite well developed, while the one of the right is rudimentary. The supernumerary nipple of the left mammary gland is also provided with a minute duct, and secreted milk during the period of lactation.

Remarks.—*Synonyms:* Polymastia, pleiomazia (accessory breasts); polythelia (*poly* + *θηλή* (thele), a nipple)—this term seems to have been first chosen by Duval.

After studying some of the best authors on pathological and comparative anatomy and evolution, one may form the following conclusions regarding the *origin, frequency, location, influence, and significance of supernumerary breasts and nipples*:

Origin.—The most fanciful ideas as to the origin of supernumerary breasts and nipples prevailed among the ancient and mediæval races of mankind, and these superstitious and, at least, baseless and unscientific explanations found their way even into medical works published not more than fifty years ago.

Meckel von Helmsbach was the first to try to explain this anatomical anomaly by the aid of embryology. According to him, in man as well as in some of the bats, Nature has "mapped out," as it were, besides the two normal mamillæ, two nipples in each axilla and one in the median line on the abdomen, a little above the umbilicus. In rare cases one or two of these, or all the five, are developed.

Darwin and Bartels, however, were the first who turned the attention of those interested in the study of defective, overdeveloped, or supernumerary organs in man to comparative anatomy and evolution; and on the hand of these two sciences offered satisfactory explanation.

Bartels states that the lemurs, a class of semi-apes, present, besides the two normal nipples, two supernumerary mamillæ, symmetrically situated on each side of the abdomen.

Mr. Darwin (*Descent of Man*, 1877, p. 37, note) observes in regard to this: "On the whole, we may well doubt if additional mammæ would ever have been developed in both sexes of mankind had not their early progenitors been provided with more than a single pair."

Professor Leichtenstern, basing his conclusions on modern embryology and the science of evolution, says: "With Darwin we explain the accessory mamma and mamillæ in man to be a *reaction* in the course of the evolution of man, standing in relation to our enormously distant ancestors of lower organization, who had more than two mammæ, and adjudge every human being the *latent capa-*

bility or inclination to produce more than two breasts. This inclination, resting upon inheritance from our ancestors, has, however, been reduced, in the course of millions of years, to *latency*, but not to such a degree as has been generally assumed, as it has been proved that accessory and rudimentary mamma and mamillæ occur much more frequently than has been formerly thought."

Frequency of Occurrence in both Sexes.—By careful observations made within very recent times it has been proved that, contrary to earlier views, the occurrence of supernumerary breasts and nipples is comparatively quite frequent, and, as far as the two sexes are concerned in this respect, the male sex offers as many, and probably a larger number of examples of this anomaly (Dr. Mitchell Bruce and Professor Leichtenstern).

Location of Supernumerary Breasts and Nipples.—In about ninety per cent. of the cases the supernumerary structures are situated below and in the same line with the normal breasts and nipples. Less frequently they are met with in the axillæ, in the umbilical region, on the thorax above the normal mammæ (*vide* my own case), and in other regions of the body. (A case of a woman is reported in the *Annals of Gynecology*, vol. 1889-90, with three legs, four well-developed mammary glands, and two vaginæ, the two supernumerary mammary glands being situated between two of her legs.)

Significance and Influence of Supernumerary Mamma and Mamillæ.—It was formerly thought that women with more than two breasts were especially "fruitful." Animals with more than two breasts usually do give birth to more than one of their species, the number of offspring being often in proportion to the number of mammæ they possess. This, however, as observation and statistics show, is not the case in the human race. Women with more than two mammæ are no more disposed to give birth to more than one child than women with the normal number of breasts (Professor Leichtenstern).

TUE

PATHOLOGY OF DIABETES MELLITUS.

By WILLIAM MOSER, M. D.,

ASSISTANT PATHOLOGIST TO ST. CATHARINE'S HOSPITAL, BROOKLYN.

THE morbid anatomy of diabetes is very varied, and has been the source of much discussion. The disease presents no lesion or series of lesions peculiar to it. It is not a distinct disease. I mean that it has no common cause; that it has no characteristic symptomatology or pathology; that its principal clinical manifestations—viz., persistent sugar in the urine, etc.—are dependent upon various morbid processes. It appears evident, from a review of the literature, that cause and effect have frequently been confounded; that at autopsies we are generally dealing with effects and not with causes appears to have been overlooked. Laboratory experiments have not enlightened us much in solving the pathogenesis of this disease. The chemical theories so far advanced have proved unsatisfactory. What are the lesions found at autopsies? Theoretically we expect to find changes in the fourth ventricle, but practically they are conspicuous by their absence. Various lesions are found in the brain, such as hæmorrhages, tubercular meningitis, etc., but they have no causal relation to the malady in question. The lungs are frequently tuberculous, at times œdematous. Sanders and Hamilton regard diabetic coma as dependent upon fat emboli in the pulmonary capillaries, with consequent slow carbonic-acid poisoning. Of course this is theory. That fat emboli do occur in some cases is beyond dispute. Frerichs ascribed the coma to acetonæmia. This, too, is theory. The kidneys quite frequently show parenchymatous changes. The epithelial cells lining the looped tubes of Henle undergo glycoëmic degeneration. I have had occasion to see a few of Ehrlich's specimens, who first made known this fact. It is an observation easy to confirm. It is recognized by the chemical reaction with

iodine. These changes are regarded as secondary. The lesions in the liver are protean. In some instances the organ is found in a condition of passive hyperæmia, in others fatty, in still others slightly cirrhotic. In short, there is nothing from which to draw ætiological deductions, as many have done. The liver cells, too, give the reaction with iodine. The heart, spleen, and intestinal tract in cases seen by the writer showed nothing of pathological interest. Most writers refer to the fatty condition of the blood in this disease. While this condition of the blood is not constant, it may at times, as in a case which I saw, be so pronounced as to give the blood a milky appearance. It was so lipæmic in this case that when placed in a glass and left standing a thick layer of fat floated on the surface. The presence of fat emboli in the lungs in these cases is apparent. Is this lipæmic condition of the blood dependent on lesions or interference with the function of the pancreas? I am disposed to advance this theory for a few cases from the fact that the pancreas plays an important part in the pathology of this disease. "Facts bearing upon the relation of pancreatic disease to diabetes have been accumulating since Cowley first discovered calculi in the pancreas of a diabetic, and Bright's pancreatic cancer in a similar case" (Tyson). In a case which I saw in the Berlin Pathological Institute an aneurysm of the arteria pancreatica was found at the autopsy. Atrophy of the pancreas is not infrequent; hypertrophy and fatty degeneration of the gland cells are sometimes seen. I have seen a few cases of the latter condition. A good specimen came under observation only recently at St. Catharine's Hospital. It must be admitted, however, that these cases (atrophy, hypertrophy, and fatty degeneration) are not so clear as those mentioned above; that the factors which bring about these changes, as well as the pathology of those cases in which the organ remains unchanged, are problems yet to be solved.

158 ROSS STREET.

Treatment of Infantile Convulsions.—"M. Jules Simon recommends the following line of treatment of infantile convulsions: 1. Empty the digestive tract by an enema and by tickling the fauces to promote vomiting. 2. If the attack continues, administer ether or chloroform on a handkerchief. 3. Administer by the mouth, or if necessary by enema, repeated doses of the following mixture: Chloral hydrate, fifteen grains; bromide of potassium, fifteen grains; syrup of codeine, ten drops; tincture of musk, ten drops; tincture of aconite, ten drops; orange-flower water, three ounces and a half—this quantity to suffice for twenty-four hours. 4. When the attack is very grave, give a warm bath and apply a small blister to the back of the neck or the epigastrium, leaving it on for three hours. Antiseptic precautions should be observed and a poultice subsequently applied."—*Lancet*.

Antipyrine in Epistaxis.—"In idiopathic epistaxis Dr. Guénot, of Laroche-en-Breuil, has frequently found a local application of antipyrine to be of great service. As a rule, he employs a solution of the strength of 1 in 5, but in mild cases a 1-in-10 solution is strong enough. He directs the patient to pour a little into the hollow of the hand and to inhale it vigorously. In the case of young or intractable children this method is, of course, not applicable. Here a syringe must be used, and after the nostrils are filled they should be compressed for a moment so as to allow the antipyrine time to act."—*Lancet*.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & CO.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, OCTOBER 28, 1893.

THE SANITARY BEARINGS OF MICRO-ORGANISMS IN A
WATER-SUPPLY.

DR. S. E. JELLIFFE has made a preliminary report of a six-months research concerning the water-supply of Brooklyn, giving special attention to those microscopical forms that are identified without culture. Like so many other of these investigations, Dr. Jelliffe's work is that of a volunteer, laboring with the zeal of a scientific man and for the good of the city where he has his abode. Massachusetts and Connecticut have done some exemplary work, through their respective State boards of health, in making lists of the organisms to be found in the drinking waters of the chief cities of those States. The individual workers, outside of New England, outnumber the officials who have sought to get at the facts in regard to city supplies. Among them are Mr. C. M. Vorce, who has made the water of Cleveland, Ohio, his study, Mr. G. W. Rafters that of Rochester, Mr. B. M. Thomas that of Chicago, and Mr. Mills and Mr. Kellicott that of Buffalo. Mr. Rafters has also made to the New Jersey State Board of Health a report on the causes and prevention of the deterioration of water in reservoirs. The last individual contributor is Dr. Smith Ely Jelliffe, whose report appears in the *Brooklyn Medical Journal* for October.

The full scope of Dr. Jelliffe's work involves weekly examinations of the Ridgewood supply for an entire year; his present report covers the first six months of that time, ending in May, 1893. His plan is to take a specimen of the water each week, involving an average of seven fields searched daily; his total fields in the six months were 1,381. His list of species numbers 112; 84 vegetable and 28 animal. A continuance of this research through the summer months is expected to materially enlarge the list.

The sanitary points brought out by this study are (1) that these species were not of themselves a material contamination of the supply, (2) that the species of more hurtful nature were not numerous in the fields, and (3) that relatively innocuous forms, which may break down under mechanical and other means, may become dangerous by affording a nutritious substance favorable to the development of pathogenic and other forms of organic life.

None too much labor, doubtless, has been expended in the identification of the *Hæmatozoon malarie*, the bacillus of typhoid fever, and the like, but the higher forms should still be remembered as having important relations to the health of a community dependent upon stored waters for their drinking and cooking supplies. As Dr. Jelliffe remarks:

"A perfectly pure water is free from all organisms, but, given a number of organized vegetable and animal forms which

may break down by mechanical or other means, there is provided immediately a more or less rich albuminous pabulum which will assist in the growth of both pathogenic and non-pathogenic organisms. In addition to this very evident proposition, many of the organisms observed give a more or less definite idea of the sources whence a water-supply is drawn." As an instance of the latter position, the author cites the fact that if the "blue-green *Alga*"—the *Oscillaria*, *Clathrocystis*, and *Palmella*—are seen, it is manifest that the water is taken from some shallow stagnant pool, and, so far as the Brooklyn water-supply is concerned, it is gratifying to note that there were only two species of *Oscillaria*, and they only in small quantities, found in the six months covered by this report. The discovery of epithelium scales in great abundance in the early spring was very suggestive of drainage contamination from barnyards along the streams and ponds contributing to the water-supply during times of excessive rainfall. This condition was found in April after the "water-famine" period had been closed by some severe rains.

Regarding those organisms, not *per se* pathogenic, but distinctly hurtful to the reputation of water supplies by rendering the odor and flavor of the water objectionable, Dr. Jelliffe reports negatively. The *Asterionella* and *Uvella* were present, but in quantities below the proportion to the cubic centimetre where they produce their objectionable fishy and acid odor and flavor. The summer months may be expected to show more numerous colonies.

Dr. Jelliffe's report is enriched with admirable illustrations and with lists and tables important to those who desire to study in similar fields. As it stands, this report can not be said to seriously incriminate the Brooklyn water-supply, but the second half-year, yet to be reported upon, may reveal more serious conditions. Considered as a volunteer task undertaken by one of our junior physicians, the report is both laborious and meritorious—a promise of good work yet to be performed.

THE FRAUDULENT DIPLOMA INDUSTRY.

RECORDER SMYTH used the most scathing language when recently sentencing a convicted dealer in fraudulent diplomas, one "Dr." Walter May Rew. The following paragraphs show that the Recorder recognizes even more fully than some of our own profession the grave consequences of this form of tampering with the general and ignorant public. Among other things, he said:

"In my judgment a more dangerous or more despicable crime could not be committed, especially by a man of the character of this prisoner, a man undoubtedly of education, who ought to be a man of refinement, and whose medical education ought to have taught him, as it does teach, that he is to act in a humane manner and not in such a way as to endanger either the lives or the comfort of his fellow beings. When such a man as he commits a crime of this character he is, in my judgment, worse than one who has not had the advantages which the defendant enjoyed.

"However, he is an old man, who at some time of his life, probably the greater part of it, has been engaged in an honorable occupation. He has been intrusted, as I understand it, by reputable members of his profession to help them with their work. Something must have happened, probably his poverty or his bad habit—his indulgence in opium—to have brought him to the disgraceful position in which he is placed to-day. I am not inclined to deal harshly with him, but an example must be made of him for the purpose of deterring other persons engaged in like business."

The Recorder then commented on the fact that the punishment of this criminal had grown out of an investigation made by one of the daily papers. The heavy expenses necessary to the successful carrying out of the inquiry—which was not so much the bringing of an individual criminal to justice as it was to point out the fact that the laws in many States of the Union were radically defective in this direction—had been borne by the newspaper without municipal assistance. The fact that there are such poor laws for the protection of citizens against the acts of ignorant pretenders indicates, as the Recorder remarked, "a most extraordinary state of affairs, one that is enough to frighten the whole country. It is astounding," he continued, "for the people of the United States to find that they should run the risk every day in some parts of this land of the terrible mischief which has been committed by men ignorant of the profession which they undertake to practice." These are timely, although caustic, sentences.

MINOR PARAGRAPHS.

PIXOL, A NEW DISINFECTANT.

The *Lancet's* Russian correspondent cites a report published in a supplement to the *Army Medical Journal*, by Dr. Eberman, on pixol, a cheap disinfectant introduced by Dr. Raptchevski. It is prepared by dissolving a pound of green soap in three pounds of tar and slowly adding a solution of a little over three ounces and a half of either potash or soda in three pounds of water. At the time of using, one part of the syrupy liquid thus formed is added to nineteen parts of water, forming a five-per-cent. solution of pixol, and it is used of this strength for disinfecting linen and for washing the hands; for the disinfection of dejecta a ten-per-cent. solution is recommended. Such a solution has been proved to be fatal to the *Bacillus anthracis*, to the bacilli of typhoid fever and cholera, and to the cocci of suppuration. It is said that the preparation costs only about two cents a pound.

ECONOMY IN HOSPITAL CONSTRUCTION.

A REPORT on matters pertaining to hygiene and public charities as observed at the Paris exposition of 1889, by Professor William H. Chandler, of Lehigh University, United States commissioner to the exposition, has recently been issued from the Government Printing Office. It is a most valuable brochure, with handsome pictorial illustrations. Professor Chandler gives an interesting comparison of the air-space for each bed, and of the cost of construction for each bed, between various representative hospitals. The Antwerp Hospital has the air-space of 1,895 cubic feet, at a cost of \$1,284; the Berlin City Hospital, 2,028 cubic feet, at \$1,757; the Johns Hopkins Hospital, 1,761 (octagon) and 1,769 (common) cubic feet, at \$6,724; and St.

Luke's Hospital, Bethlehem, Pa., 2,045 cubic feet, at \$1,400. This is certainly very creditable to the designer of St. Luke's Hospital.

HAMBURG'S CENSORSHIP ON TELEGRAMS RELATING TO CHOLERA.

The history of sanitary conferences is not such that confidence is inspired by the promulgation of their conclusions. It is but a few months since the Dresden conference was held at the instigation of the German Government; and yet the Hamburg director of telegraphs has been authorized to exercise a censorship of all telegraphic matter sent from that city concerning cholera, in order, as it is alleged, to prevent the dissemination of false and sensational reports.

THE TREATMENT OF SYPHILIS AND MUTUAL AID SOCIETIES IN GERMANY.

La Province médicale for September 30th states that a large number of the German mutual aid societies refuse, by their by-laws, all assistance to those of their members that incur venereal diseases. The Prussian ministers of the interior, for hygiene, and for commerce have requested these societies to extend to their members affected with venereal diseases the medicines and professional services necessary to secure recovery. They urge the utility, from the standpoint of public health, of the prompt cure of these patients.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 24, 1893:

DISEASES.	Week ending Oct. 17.		Week ending Oct. 24.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	0	0
Typhoid fever.....	32	16	43	16
Scarlet fever.....	41	6	60	7
Cerebro-spinal meningitis....	2	2	7	5
Measles.....	63	3	93	3
Diphtheria.....	129	18	186	40
Small-pox.....	20	3	16	3

The Illness of Sir Andrew Clark.—We learn with great regret that Dr. Clark has been instantaneously stricken down by a cerebral hemorrhage. He was conversing with a patient when the blow fell. Two days previously he had occupied the chair as president of the Royal College of Physicians on the occasion of the Harveian oration.

A New Special Hospital.—The conductors of a newly proposed institution have filed a certificate of incorporation under the style of the New York Throat and Nose Hospital. The eye, the ear, and the lungs will receive due attention as well as the organs named in the title. Among the managers of this institution for the first year are Dr. E. J. Bermingham and Dr. J. J. Henna.

The New York Hospital.—Under the will of the late Charles B. Beck, this institution will probably receive about two hundred thousand dollars.

Change of Address.—Dr. W. H. Bates, to No. 64 East Fifty-eighth Street.

The late Dr. Edwin T. Doubleday.—At a stated meeting of the New York Hospital Alumni Association held on April

28, 1893, the following preamble and resolutions were authorized :

Whereas, It has pleased the Almighty Father, in his omnipotent wisdom, to remove from us Dr. Edwin T. Doubleday, a past house officer of the New York Hospital, an original member of this association, and its secretary since its inception; and

Whereas, Dr. Doubleday was, throughout his professional career, a devoted student and an accomplished practitioner, both in the hospital and in his private work; and

Whereas, He was a gentleman who by his kindly nature and his thoughtful interest in others endeared himself to all with whom he came in contact; therefore, be it

Resolved, That we, the members of this association, do hereby express our deep grief at his untimely death and our sense of personal loss. And be it further

Resolved, That we tender to his bereaved family our profound sympathy in their affliction. And be it further

Resolved, That a copy of the foregoing be presented to the family of the deceased and that it be sent to the medical journals of this city.

[Signed.] CHARLES A. POWERS, M.D.,
GEORGE A. RICHARDS, M.D., } Committee.
GEORGE H. COBB, M.D., }

The Death of Mr. Charles Clay, of Manchester, England, took place on September 19th. He was ninety-one years old. His first successful operation on a large ovarian tumor was done in 1842, by the long incision, and about five years later he did his first total removal of the uterus for fibrocystic growth. His innovations were opposed by not a few, but he had the support of Simpson, Braithwaite, and others to the extent that his services as an operator came into such great demand that about 1860 he was worn out and obliged to retire for a time. Clay was an archæologist and numismatist of renown. At one time he was the possessor of the largest collection of American silver and copper coins in the world—a collection that was purchased by the United States. He collected over one thousand different editions of the Old and New Testaments, which were sold for a very high price. He wrote on the rare topic of the currency of the Isle of Man. Mr. Clay was interested in geology, and published his *Geological Sketches of Lancashire* as early as 1839. He was formerly the senior medical officer and lecturer on obstetrics at St. Mary's Hospital, Manchester. He was the author of a *Handbook of Obstetric Surgery*.

The Death of Dr. Charles H. Fisher, of Providence, R. I., is reported as having occurred on Saturday, the 21st inst. The deceased was secretary of the Rhode Island State Board of Health.

The Death of Dr. John C. Peters, a retired New York practitioner, took place at his home, at East Williston, Long Island, on Saturday, the 21st inst., in the seventy-sixth year of his age.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 15 to October 21, 1893:*

HARTSUFF, ALBERT, Lieutenant Colonel and Deputy Surgeon General, is relieved from duty at Fort Omaha, Nebraska, and ordered to report in person to the commanding general, Department of California, for duty as medical director of that department, to relieve SMITH, JOSEPH R., Colonel and Assistant Surgeon General. Colonel Smith, on being relieved by Lieutenant Colonel Hartsuff, will proceed to Governor's Island, New York, and report in person on December 4th to

the commanding general, Department of the East, for duty as medical director of that department.

STARK, A. N., First Lieutenant and Assistant Surgeon, now at Fort Clark, Texas, will proceed at once to Fort McIntosh, Texas, and report to the commanding officer for temporary duty with troops in the field at Carrizo, Texas.

WOODSON, ROBERT S., First Lieutenant and Assistant Surgeon, now temporarily at Fort McPherson, Georgia, will return to his proper station, Fort Barrancas, Florida.

Society Meetings for the Coming Week:

MONDAY, October 30th: New York Academy of Medicine (Section in Public Health, Legal Medicine, and Medical and Vital Statistics).

TUESDAY, October 31st: Medical Societies of the Counties of Queens (semi-annual—Garden City) and Rockland (semi-annual), N. Y.; Boston Society of Medical Sciences (private).

WEDNESDAY, November 1st: Society of the Alumni of Bellevue Hospital; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton), N. Y.; Bridgeport, Conn., Medical Association.

THURSDAY, November 2d: New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua; Medical Society of the County of Orleans (annual—Albion), N. Y.; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

FRIDAY, November 3d: Practitioners' Society of New York (private); Baltimore Clinical Society.

SATURDAY, November 4th: Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

Answers to Correspondents:

No. 414.—The pathologists of all well-equipped hospitals are engaged in bacteriological work.

No. 415.—We do not think any medication will be of assistance.

No. 416.—If possible, postpone the operation until the child is five or six years old.

Proceedings of Societies.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Fifteenth Annual Congress, held in New York on Monday, Tuesday, and Wednesday, May 22, 23, and 24, 1893.

The President, Dr. MORRIS J. ASCH, of New York, in the Chair.

(Continued from page 452.)

Buccal Voice.—Dr. J. SOLIS-COHEN, of Philadelphia, read a paper on this subject. (To be published.)

Dr. G. M. LEFFERTS, of New York: Eighteen years ago I removed a papilloma from this man's larynx, and for ten years or more he was perfectly free from any signs of recurrence.

I do not know that I can add anything to what Dr. Cohen has said and to what will be demonstrated by an examination of the patient. The examination will speak much more strongly than any words of mine. I think the result that I saw there this morning is an exceedingly interesting and favorable one. There are no signs of any recurrence of the growth, but the

appearance is very curious. The parts are exceedingly difficult of identification.

The question of main interest to me at present is how the man articulates. I think you will all agree with me that it can only be by the use of the lips and tongue; this can be seen if you watch him closely. I had him phonate with his mouth wide open, and the pillars of the fauces remained motionless. Of course, it is out of the question that any sound comes from the region of the larynx.

Dr. DELAVAN: I think that the voice with which this man speaks is vastly superior to the artificial voice produced by a mechanical larynx, for the reason that with the latter the voice is so artificial, resembling as it does a boy's toy whistle.

There is one point in connection with Dr. Solis-Cohen's case which I consider one of its most important lessons. The case was not treated antiseptically. To my knowledge, two somewhat similar cases operated on in this city nearly died from iodoform poisoning. In a case of my own, operated on by one of our prominent surgeons for epithelioma of the tonsil, death almost resulted from the same cause. Fatal cases have been reported by foreign surgeons. The area of the wound left by the operation is so enormous that it is not difficult to suppose that rapid absorption of the drug may take place. In view of this danger, some substitute for the iodoform dressing might be used or the wound be treated without such dressing, as Dr. Cohen has indicated.

Dr. WRIGHT: I think it is impossible to keep a wound in this location aseptic. It is useless to attempt it. The wound communicates with the mouth, which is the source of all evil in the bacteriological way.

Dr. LANGMAID: I can not agree with Dr. Lefferts that the sound this man makes is produced by the tongue and lips. From the very superficial examination I have made, I am of the impression that the voice is produced by vibrations of the soft palate, which obtain re-enforcement in the nasal and buccal cavities. The articulation sound is produced by the teeth. It would be very interesting to notice what consonant sounds he is unable to produce. I hope it will be possible for Dr. Cohen to put this patient through a regular course of vocal production to see what he can do and what he can not do in the way of the gamut—the elevation and depression of tone.

Dr. SOLIS-COHEN: Of course the articulation is done by the tongue and lips, but the phonetic reed must be lower down. There is some tissue that is producing the sound. For the production of sound all we need is something to vibrate. Perhaps in this case the distended pharyngo-cutaneous structures act as a supplementary lung, driving the air through this phonetic reed, whatever it is, and the sound is articulated by the tongue and lips into speech, as in the normal condition.

The Cautey in Staphylotomy.—Dr. T. A. De Blois, of Boston, read a paper with this title. (See page 475.)

Dr. CASSELBERRY: I should like to ask Dr. De Blois if the pain following the operation by means of the galvano-cautey is not more severe than in cases where the uvula is simply clipped off with the scissors?

Dr. F. I. KNIGHT: It has always seemed to me that the use of any instrument which simply cuts the relaxed mucous membrane of the uvula transversely was wrong. It leaves a very painful sore. For years I have always drawn the relaxed membrane so well forward that when I use the scissors the cut is an oblique one and the raw surface presents entirely behind, as in Dr. De Blois's operation. We should have that object in view—to get the raw surface behind, and as a result there is almost no soreness on deglutition. Dr. De Blois spoke of cutting the muscle; it seems to me the object is only to cut the relaxed mucous membrane.

Dr. De Blois: In reply to Dr. Casselberry I would say that I had my own uvula cut with the scissors; it was cut off perfectly square, and for about four days I suffered very much, and was nearly starved. By the use of the galvano-cautey I have not yet seen any patient who suffered as much as I did. As regards Dr. F. I. Knight's remark concerning the structure of the appendage, I always supposed that the azygos muscle ran to the very tip of the uvula. I usually cut it off within half an inch of the velum.

A Case of Sarcoma of the Soft Palate, illustrating the Degeneration of a Benign (Papilloma) into a Malignant Growth; Removal of the Soft Palate; Death.—Dr. W. K. SIMPSON, of New York, read a paper with this title. (See page 498.)

Dr. WRIGHT: It is very difficult for me to conceive how such a case as this could be regarded as anything but malignant from the start. The fact that the microscopic examination was wanting seems to me almost a proof that it was malignant. This uncertainty of gross appearances was impressed on my mind during the past winter. A patient was operated on at Roosevelt Hospital for a papilloma of the subglottic space. An external incision was made, and a growth, apparently typical of papilloma, was seen. Dr. Asch, I believe, saw the case, or at least was present at the operation. There was no doubt in any one's mind but that we had to deal with a simple papilloma. A microscopic examination showed it to be an epithelioma, and the larynx was removed at a subsequent operation.

It is very hard, even microscopically, to prove or disprove these cases. You can not tell what there may have been below the papillomatous formation. We know that very frequently in syphilis, tuberculosis, sarcoma, and carcinoma the surface of the growth is covered by a papilloma, and unless you cut deep into the tissues it is impossible to say whether you have to deal with a benign or malignant growth.

The case related by Dr. Simpson ran the ordinary course of a malignant growth from the beginning. It is of course perfectly possible, according to modern pathological laws, that a malignant growth may appear in a benign tumor in the same way as it may appear in normal tissue; and that adds another element of doubt to these cases. It is now thought that a malignant growth is due solely to the potential energy in the cells, which will finally explode itself in the form of infiltration. In other words, a form of cell which does not contain this potential energy does not show this tendency to proliferate. It can not acquire the potential energy if it is wanting from the beginning.

Dr. J. O. ROE, of Rochester: I agree with Dr. Wright that it is impossible to say whether this potential energy is always present or not from the start. I have in one or two instances, however, seen tumors gradually change from a benign to a malignant form, as shown by careful microscopic examinations made at different times. One case was an angioma of the nose. I removed the growth, which was of quite large size, growing from the outer wall of the meatus. This growth was examined by competent pathologists, who pronounced it an angioma. It returned, and I removed it altogether three times. Each time it reappeared there was less vascularity—loss of the angiomatic character—and more sarcomatous elements, which after the third removal were very pronounced. The patient left the city for about two months. On his return only a small portion of the growth had reappeared, and before it had caused any marked obstruction of the nostril the patient died from asthenia. In this case there was an unquestionable transition from a benign to a malignant growth.

Dr. SWAIN: I have taken occasion in another place to report a case which is in point in the present discussion. The patient

was a man, sixty-three years old, who, five or six years before I saw him, became the subject of a tumor in the subglottic space, which was diagnosed as a simple myxoma. The patient had refused operation and the tumor was allowed to stay there, giving rise to occasional attacks of hoarseness and cough. Later these symptoms became more pronounced. An examination revealed a well-marked tumor of the false vocal cord, invading the anterior part of the true vocal cord. The growth was unhesitatingly pronounced an epithelioma; although it had some of the appearances of a papilloma, there was considerable infiltration. The original tumor was still *in situ*. The case seemed a very favorable one for thyrectomy, and the operation was done. The entire mass was removed, together with the original tumor. Sections were made of the original tumor and the epithelioma. The tumor itself was a simple myxoma, with an unusually large number of mucous glands in it; these had begun to undergo degeneration, as we see in a true adenoma of the mammary gland. The epithelioma itself was an absolutely typical one, with the pearls of epithelial cells deeply invading the structures beneath, down to the cartilaginous framework of the larynx.

The man recovered from the operation and died from an intercurrent pneumonia. The interesting point of the case is that the original tumor had existed for at least five years before the malignant growth made its appearance. That the irritation caused by this growth started up the potential energy of the cells producing the epithelioma is at least probable if not almost certain. Another interesting point is the fact that in the original growth itself the glandular tissue was undergoing this transformation from the appearance of a true adenoma to that of an epithelioma.

DR. GLASGOW: The subject of benign growths becoming malignant is an interesting one. In the case reported by Dr. Simpson, the weak point is the lack of a microscopical examination of the original growth. Semon has gone very thoroughly into this subject, and from his statistics it appears that this change occurs very rarely. From those statistics I have made up my mind, somewhat unwillingly, that such a transformation is barely possible. Such changes, however, take place externally, and I do not see why they should not take place in the larynx. A case has come under my observation that I considered originally to be a benign growth—a papilloma—and subsequently it seemed to change to a malignant growth; however, one important element in the case, the microscopical examination, was wanting. It occurred early in the seventies, and was a case of large multiple papillomata, nearly filling the larynx. I removed the larger part, but left a portion of the bone. About a year after the operation he came to see me. He was suffering great dyspnea, and on examination it was found that the growths had reappeared and completely filled the larynx. I was just about to leave for my summer holidays, and I told him that I would not be able to perform a thorough operation at that time, but would simply relieve his dyspnea, which I did by clearing out a large portion of the growths. I noticed then that this new growth had an entirely different appearance from the old one. The original growth had the ordinary pink hue of the papilloma, while this was very white. It had grown very rapidly, and taking this fact into consideration, and its changed appearance, as well as the man's cachectic look, I was inclined to believe that this new growth was malignant. The man died six months later.

If it can be proved that a benign growth may be changed to a malignant one by operative interference, it has a very important bearing on these operations, as in many cases removal of these growths is not absolutely demanded, as they simply cause inconvenience or some change in the voice.

DR. F. I. KNIGHT: This is the topic on which I asked for some information yesterday. I think that the testimony of the individual members here will be worth a great deal more to us than years of theorizing and microscopical work. As I said yesterday, I have never encountered but one case of tumor of the larynx wherein a growth which I had diagnosed as a simple papilloma proved to be malignant later. That case very probably was malignant from the beginning. It was a case of multiple papillomata, as was Dr. Simpson's. I should consider in his case that the probabilities are in favor of the growth having been malignant from the start.

In regard to the value of a microscopic examination of these bits of tissue which we remove from the larynx, if we get any positive evidence thereby, well and good, but I do not think the negative evidence is worth anything. I feel that I can judge better by the clinical aspect of the case, by its appearance, and by the changes which take place, than I can from the microscopic examination, and I should like to have the opinion of the members on that point; also let each one put on record to-day any case that has come under his observation in which a supposed benign growth became malignant.

DR. CLINTON WAGNER, of New York: In regard to the degeneration of a benign into a malignant growth, I wish to give an instance which came under my observation. The patient, a man, some years ago came to my clinic at the Metropolitan Throat Hospital. At that time there was a growth about the size of a large pea on the right cord, near the anterior commissure. I regarded it as a papilloma, and suggested the removal by the forceps, which could have been done at that time without difficulty. The patient declined operation and sought treatment elsewhere.

Twelve months later he again consulted me, at which time the whole box of the larynx was almost completely filled with growth. Several large pieces were removed by means of the forceps, but as the growth was found to extend downward below the cricoid cartilage, and as dyspnea was becoming more urgent each day, tracheotomy and thyrectomy were performed, the growth removed, and the patient discharged in a few weeks from the hospital. The tumor was submitted to Dr. Heitzmann for examination, who pronounced it a simple papilloma which had grown from a highly inflamed base, and, if it recurred, it would most likely come as a malignant growth. Both the curette and galvano-cautery were employed to secure thorough destruction of the attachments of the growth. Several months later the growth reappeared on the very same spot; it grew very rapidly. A portion of the tumor which was submitted to Dr. Heitzmann for microscopic examination was pronounced to be epithelioma. I resected the entire right half of the larynx. The man died fifteen days after the operation.

In another case—a sessile growth upon the right cord, the greater portion of which I removed—the patient, feeling so much improved, disappeared from observation; he returned for further treatment six months later. The growth filled the larynx almost completely. Tracheotomy and thyrectomy were performed, and the mass thoroughly removed. One microscopist pronounced the growth a simple papilloma, another a sarcoma, while still another an epithelioma papilloma. My own idea was that it began as a papilloma, but recurred as an epithelioma.

DR. F. I. KNIGHT: I think, in the first case reported by Dr. Wagner, the pathologist was probably wrong. A malignant growth developed in seventeen weeks at the site of operation, which shows that it was probably malignant at the time of first removal, or, at any rate, one would hesitate to accept it as a benign growth at that time.

Dr. REHRIG: It seems to me that the clinicians have entirely too much respect for the microscopist, and that the microscopist has entirely too much contempt for the clinicians. One is as liable to make mistakes as the other. The microscopist makes a number of sections from a growth, but it is impossible to say whether we have not left behind the cells which in the future will produce a malignant growth apparent even to the naked eye. We must go back and change the conception we have of the present laws of pathology. We must learn something more about the laws of biological growth. It can not be settled by bringing up this case and that case, because the question will always arise whether we have not left behind the malignant part of the growth, or whether the part of the mass selected for examination contained the characteristic evidences of its nature. Without a microscopic examination at the first, of course we, as clinical diagnosticians, lay ourselves open to justifiable criticism.

Dr. SWAIN: I do not see why Dr. Knight takes exception to the case narrated by Dr. Wagner. If that growth was malignant from the start, why was not the entire growth malignant? Is it possible for the base of a growth to be malignant, and its outermost or oldest portion to be non-malignant? I think not. We must look upon the portion of the growth that is uppermost as its oldest portion. That is a fair inference. If this portion of the growth was diagnosed as papillomatous, why was not the original growth a papilloma which had undergone this degeneration the occurrence of which we are discussing? A papilloma is a fairly easy growth to diagnose in one way. It has a certain characteristic appearance which a sarcoma or epithelioma has not, and if the upper portion of the growth in Dr. Wagner's case was pronounced by a skilled microscopist as being a papilloma on an inflamed base, I should like to know why that is not just exactly what we might have. Perhaps through the prolonged irritation of the base by the papilloma the epithelioma was developed.

Certainly, as Dr. Wright says, the general laws of pathology are still unsettled; but if there is any truth whatever in the Cohnheim theory of the potential energy springing out of the original embryological elements, I think just such a case as Dr. Wagner relates is one in point, and I do not think it should be ruled out on the ground that the pathologist made an error.

Dr. WRIGHT: In speaking of the malignant growths, I think we must rule out microscopical evidence of small-celled sarcoma. Under the microscope it is easy enough to recognize the spindle-celled or giant-celled sarcoma, but with the small-celled variety the clinical appearances are much more reliable than the microscopic. In the case of a small-celled sarcoma you will get all sorts of diagnoses from the microscopists. Without the history it is impossible to get two men to agree. Small, round-celled sarcoma, granulation tissue (syphilitic or tubercular), and lymphoid hypertrophy are frequently indistinguishable under the microscope.

Dr. MULHALL: I desire to ask a question on a subject about which I must confess a certain amount of ignorance. Is sarcoma of the upper air passages ever operable? In other words, is it justifiable to operate on sarcoma of the upper air passages? Does any one know of a case in which recurrence and death have not followed? If, perhaps, we saw these cases early enough, recurrence might be prevented, but, unfortunately, we do not see them usually until hæmorrhage and obstruction have taken place.

I would suggest an excellent subject for a paper to one who has access to the literature the following: "Is sarcoma of the upper air passages ever operable, in the light of past experience?"

Dr. FARLOW: Several years ago I removed with the snare

an outgrowth from the left side of the anterior part of the septum. The growth was pronounced by the pathologist a fibro-sarcoma. The operation was performed four years ago, and no recurrence has taken place, either on that spot or elsewhere.

Dr. B. ROBINSON, of New York: I know of one case of sarcoma which has gone on for three or four years after operation without signs of recurrence. The operation was performed by Dr. Bull. The man resides in Newport and is occasionally under my observation.

Dr. GLEITSMANN: I exhibited a case of primary sarcoma of the tonsil to the members of the Section in Laryngology of this Academy, showing the patient both before and after operation. The operation was performed two years ago, and thus far there has been no recurrence. He came to my clinic at the German Dispensary presenting a growth of the tonsil, which was pronounced by Dr. Heitzmann to be a sarcoma. The patient was referred to the surgeon of the German Hospital, who performed tracheotomy, cleaned out the triangular space, and excised a part of the lower maxilla and the tonsil. In addition to that he found that the larger part of the tongue was also infiltrated, and removed it almost entirely, leaving only the tip. The patient is able to make himself understood by whispering.

Dr. A. W. DE ROALDES, of New Orleans: As a newly elected member, I had not intended taking a part in the discussions of this meeting, but I feel it my duty to report in this connection a case which has occurred in my own family, and which illustrates very well a point made by Dr. Wright in regard to the difficulty of diagnosing with the microscope sarcomatous growths when they affect adenoid or lymphoid organs like the tonsil.

In my own house, some years ago, I had occasion to remove a tonsil which I considered at the time to be a fibroid tonsil and which caused a great deal of trouble. It had been treated previously by several family physicians, and for years repeatedly touched with caustics. I operated the case in my office; there was no hæmorrhage whatsoever, and I sent the lady home and gave the matter no further thought, when, an hour after, I was hurriedly summoned and found that I had to deal with one of the most frightful cases of post-operative hæmorrhage I have ever seen. The lady had taken some warm milk; this, I presume, favored the hæmorrhage by dissolving the clot. Anæmia of the brain, convulsions, and other very severe symptoms were the result of this great loss of blood. I had kept the removed tonsil, and sent a portion of it to the late Dr. H. D. Schmidt, pathologist of the Charity Hospital, who was then considered one of our best microscopists. His report came in a few days later, in which he pronounced the growth a round-cell sarcoma. This report, which took me by surprise, worried me very much, and about three weeks later I sailed for England and had the lady examined by two or three well-known men. Nothing suspicious could be found from a clinical standpoint. I then went to Paris and had the specimen carefully examined in Dr. Cornil and Dr. Ranvier's laboratory. There also it was pronounced to be a round-cell sarcoma.

The tonsil was removed six years ago; since then I have watched the case attentively, and there has been no sign of recurrence.

I to-day report this observation simply to show how difficult it is to base one's diagnosis of such cases on the microscopical examination. Supposing in my case that, influenced by the microscopical reports, I had hastened to remove the whole tonsil by a subsequent operation, I should be able to report to-day to you a case of sarcoma of the tonsil successfully operated, and in which six years after no recurrence had taken place.

In conclusion, I think we should be very prudent in such cases and not trust too implicitly the microscope when it comes to diagnosticate suspected sarcomatous growths in adenoid or lymphoid organs like the tonsils.

While I use the microscope in my own hospital—and I have made the microscopical department a feature of the institution—and while I insist that, as far as possible, no growth should be removed before hearing from our pathologist, still I have learned by experience, as some other observers have recently pointed out, that the microscope is apt to lead to some very serious errors of diagnosis in cases as above referred to.

Dr. SHURLY: I can confirm what has been said about the dangers of relying too much on the report of the pathologist. I do not know of a single case in my own practice in which a benign growth has become malignant. I can conceive, however, theoretically, of such a degeneration or evolution occurring. It is a very short step from the homogeneous to the heterogeneous formation. I believe general surgeons are almost all agreed that a benign growth of the mammary gland may become malignant. Until we learn the true pathology of these growths I do not see how the question can be settled. Very many people in this country, no doubt, live for many years with a papillomatous growth in the larynx and never come under special medical observation. I have frequently found them in persons whom I examined at my own solicitation. We do not know how often malignant growth may have been preceded by benign growths, because we have no accurate statistics on this point.

Dr. SIMPSON: The lack of a microscopic examination of the original growth in my case is possibly a weak point. My idea was to invoke a discussion on this subject. The discussion has really convinced me that my weak point is not quite as weak as at first supposed. If clinical evidence is of any value whatsoever, the original growth was undoubtedly a papilloma. I do not think we should criticise the microscopists or the microscope, and to a certain extent we must accept their statements.

One important point in connection with this subject is the matter of irritation. It is maintained by many that irritation is primarily the cause of malignant growths. When we operate on a laryngeal growth, apparently benign, it is almost impossible to avoid irritating or wounding the surrounding tissue, and this, I think, forms a focus for future degenerative changes. In the case reported by me the potent factors of irritation were the cautery and the lactic acid. You could almost see these benign growths become indurated and change their appearance.

(To be continued.)

FIRST PAN-AMERICAN MEDICAL CONGRESS.

Held in Washington on Tuesday, Wednesday, Thursday, and Friday, September 5, 6, 7, and 8, 1893.

SECTION IN GYNECOLOGY AND ABDOMINAL SURGERY.

(Concluded from page 388.)

An Inquiry into the Ætiology of Mental Disturbances following Operations upon the Pelvic Organs.—Dr. GEORGE H. ROHÉ, of Catonsville, Md., read a paper upon this subject. (See page 437.)

Dr. JOSEPH PRICE, of Philadelphia, was of the opinion that many women had insanity as a coincident and not a result of an operation upon the genital organs. He had removed patients from insane asylums several times to operate upon their pelvic organs, and in some of them the mental disorder had been relieved as a result. He believed with the author that a considerable percentage of women in insane asylums would be

cured if relieved of pelvic and abdominal disease. There was, in his opinion, a decided relation between fibroid disease of the uterus, ectopic gestation, and disturbed mental condition. Among the eighty-six women upon whom he had operated for ectopic gestation, he did not think one had been entirely sound mentally before the operation. He had also seen grave mental disorder relieved by the relief of uterine displacement. He believed that hysterectomy was sometimes followed by mental trouble, and often dreaded the operation on that account.

Dr. A. F. CURRIER, of New York, believed that all cases bearing upon this subject should be recorded. The subject was as yet too immature to draw definite conclusions. He had seen three cases bearing upon the subject—one of mania and two of melancholia. The first had followed the removal of diseased appendages, the patient becoming wildly delirious in twenty-four hours after the operation and forty-eight hours later becoming perfectly rational. He had attributed the condition partly to the shock of the operation and partly to the influence of ether. The second patient had become melancholy twenty-four hours after a Hegar operation and had sunk steadily, without fever, though taking an abundance of food, and died on the sixth day. The third patient had been operated upon for lesions of the cervix and perinæum six weeks after a very prolonged labor. The operations had been entirely successful, but melancholia had supervened about three weeks later and she was now entirely helpless.

Dr. ROHÉ insisted that a post-operation insanity was a septic insanity and this had been verified by the cases narrated. Many insane women were very anæmic; this suggested the importance of proper nourishment as a means of prevention. Unfortunately, with many women with a predisposition to insanity, this was a precaution which was out of their reach.

The Extraperitoneal Treatment of the Stump in Abdominal Surgery.—Dr. JOSEPH PRICE, of Philadelphia, defended this method of treatment after an extensive experience. Those who criticised it showed plainly that they had not the proper understanding of the method. It would be unreasonable for him to give up a method which had served him so well and adopt one which was based on theory rather than actual experience. His experience included one hundred and eleven cases. In all these cases there had been gradual strangulation and contraction of the stump, with free flow of serum for several days, with no offensive odor, and final dropping of a button of dead and desiccated tissue. Most of those who had adopted the new method had made failures with the old one. By the new method he referred to that one in which the cervix was retained in the pelvis and was covered with peritonæum. The old method took much less time than the new one, required few ligatures, and had been in successful use by some of the most skillful surgeons in the world for twenty years. If the *serre-neud* was properly applied in this method it would never slip, and the intestine would never become entangled in the stump if the operation had been properly performed. If this method was to be abandoned he would accept that of complete extirpation as a substitute, but the risks in the latter, he believed, were greater than in the method which he practiced.

Report of One Hundred Operations done for Serious Structural Disease of the Abdominal and Pelvic Organs of Women.—Dr. I. S. STONE, of Washington, D. C., read a paper with this title. (See page 468.)

Deductions from my First One Hundred and Ten Laparotomies for Appendicitis, with Report of Experimental Investigation.—Dr. J. B. MURPHY, of Chicago, read a very interesting and important paper with this title. The subject under consideration was still unsettled; there was still disagreement as to its pathology and as to the probable results of medi-

cal as opposed to surgical treatment. It was also impossible to foretell the final results in many of the cases which had been under observation. In some cases the condition was a dangerous one, in others it was not. The classification of the disease, based upon the experience which the author had had, would be as follows:

1. A simple catarrhal form.
2. A form with ulceration of the mucous membrane of the appendix, with its subdivisions.
3. An ulcerative form with infection.
4. A gangrenous form, either partial or complete as to the extent of tissue involved.
5. A gangrenous form with and without perforation.
6. A form in which infection of the peritonæum was the salient point.
7. A form in which peritonitis was most prominent.

The location of the appendix varied greatly, and this should be considered in operating. The causes of the disease were numerous. In many cases it was an infection process; there might be in addition the irritation of a foreign body; in other cases it followed pressure atrophy, with infection from fecal concretions; in other cases there was a specific infection, as from syphilis, tuberculosis, or typhoid fever. Perforation occurred in seventy per cent. of the cases. The catarrhal form was not usually serious, and generally accompanied enteritis; but if there was retention of material within the appendix, the result might be serious. Gangrene might be complete, even in the catarrhal form and without perforation. Pressure atrophy with perforation might occur, the latter being due to fecal concretions. The specific infections were ulcerative conditions similar to those which occurred in other portions of the intestines. Suppurative peritonitis might occur with ulceration alone—in other words, without perforation. If ulceration was followed by perforation the result might be fatal, as with similar lesions in other areas of the intestinal tract. Partial gangrene might occur as the result of pressure of a foreign body over a limited area, or from the pressure of contiguous fluids; complete gangrene from twists and dislocations of the appendix or its attachments. In such cases the peritonæum might be uninfected. If an abscess had formed, the danger was small before perforation had occurred; after that accident fatal peritonitis was likely to result. The abscess, at first small, might gradually increase, with adhesion to contiguous viscera, and perforation occur either into a viscus or into the peritoneal cavity. This process might be of very long duration, even many months. The speaker was confident that this disease always began in the peritoneal cavity, and, because the abscess might be adherent to the parietal peritonæum and open outwardly, the mistake was made that it had begun in the cellular tissue. The resulting peritonitis might be dry or suppurative, local or general, with or without the development of ptomaines. When perforation first took place the symptoms might not be alarming; there might even be a feeling on the part of the physician that the patient was recovering without any serious lesion. It might be from four to seven days after perforation before collapse took place. During this period ptomaines were being developed and absorbed; and after collapse death resulted in a few hours. The unvarying symptoms at the beginning of the disease were sharp pain in the right iliac region, nausea and vomiting, localized tenderness, and elevation of temperature. They might vary in intensity, but were all present in the first twenty-four hours of the disease. An operation after collapse was almost certain to be useless. Collapse was brought about and influenced by the character of the fluid in the abscess, by its quantity, and by the changes which took place in it and the infectious conditions resulting. Errors of diagnosis need seldom be made. With

the author such an error had occurred only three times in a hundred and seventeen cases. The dangers were those which were due to the disease and those which were due to the operation. The disease was fatal without operation in about twenty-seven per cent. of cases. In the author's one hundred and seventeen operations, eleven had resulted fatally. The danger from the operation itself was comparatively *nil*. The incision should be made over the cæcum, and the diseased area separated by gauze packing from the rest of the abdominal cavity. The diseased structures might be removed or not according to the urgency of the symptoms. The gauze might be retained from ten to twelve days, and the patient notified that the structure could be easily removed at a subsequent period in case of a recurrence of the trouble. Irrigation had never been practiced by the author, except in the extraperitoneal cases. The introduction of fluids into the peritoneal cavity injured the epithelium and favored septic absorption. Idiopathic peritonitis did not exist. Many cases which were called by this name were cases of appendicitis.

Appendicitis.—This was also the subject of a paper by Dr. R. T. MORRIS, of New York. The key to the understanding of this disease was the presence of a soft distensible tube of mucous membrane and its underlying adenoid tissue inclosed within a rigid muscular and serous tube. The histological and anatomical elements included in the appendix were all contributory to the inflammatory condition. The condition was a mixed bacterial infection, an infectious exudative inflammation. Bacteria having invaded the tissues might remain a long time before conditions arose which would favor their development. The forms of the disease included a simple catarrhal process, a process with destructive changes in the tissues involved, and a process with extensive necrosis of tissue and spasm of the muscle fibers. There might also be an associated phlebitis, lymphangitis, thrombosis, and peritonitis. The disease might be precipitated by violence or traumatism of different forms, or by the specific infectious element of typhoid fever, tuberculosis, *la grippe*, etc.

The epithelium of the mucous membrane of the appendix being once destroyed, infection and necrosis were always possible and imminent, though the process might take years for development. The outside of the appendix might be normal in appearance when its mucous membrane was necrosed. When the peritonæum became infected there was a process of supuration with walling off of the infectious products, then bacterial change, and finally perforation and possibly general peritonitis. The severest and most painful cases were those in which there was spasm of the muscular layer, the contents of the tube being crowded toward the tip of the organ. Either constipation or diarrhea might be present as the result of ptomaine infection. The disease starting in the appendix would involve all the structures of the contiguous bowel sooner or later. The bilious vomiting of appendicitis was due to reversed peristaltic action. Colic was the salient symptom in some cases and septicæmia in others. The indication was for an early operation in all cases on account of the infectious character of the disease. In the simplest cases an incision only an inch and a half long, following the line of the aponeurosis of the external oblique muscle, was required. The longitudinal muscular ribbon of the colon should be sought, and the appendix drawn out and ligated with catgut and removed, the mucous membrane being turned inward. In severer cases an incision three inches long was required, the patient, in such cases, being in the Trendelenburg posture. In the severest cases, with abscess and extensive induration, the incision should be four inches and a half long, and the cavity should be cleansed with saline solution and peroxide of hydrogen, and then packed with wicking or

absorbent gauze, with a large outer dressing. The prejudice which many showed on this subject was unreasonable, for a structure was concerned of no known functional importance which when once diseased would always be a source of danger.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Nineteenth Annual Meeting, held in Indianapolis on Wednesday, Thursday, and Friday, October 4, 5, and 6, 1893.

(Continued from page 481.)

SECTION IN OBSTETRICS, GYNÆCOLOGY, AND ABDOMINAL SURGERY.

Dr. ARTHUR W. JOHNSTONE, of Cincinnati, Chairman.

Ovariectomy in the Aged was the title of a paper read by Dr. RUFUS B. HALL, of Cincinnati. The author confined his remarks to patients who were seventy or more years of age. He said it was generally conceded as true that any operation upon the old did not promise such good results as the same operation would upon the young or patients in middle life. Especially was this true in reference to all abdominal operations requiring a hard strain upon the system from shock or from traumatism to vital organs during the operation, as was not infrequently the case in the removal of large ovarian tumors. He maintained that the death rate was not greater than that which usually followed the same delayed class of operations on women between forty and fifty years of age. He had done but three ovariectomies upon women above seventy years of age. In each of the first two cases the friends had hesitated to have the operation done, on account of the advanced age of the patients, and the operation had been deferred until the patient was in *extremis*.

Dr. Hall then detailed three interesting cases of ovariectomy performed on patients aged respectively seventy years, seventy years and six months, and seventy-two years. Judging from the low mortality in the cases reported and from the work of the best-known operators, the author was constrained to believe that ovariectomy in old women, if the kidneys were healthy, was as safe as in middle life.

The Value of a Close Observation of Other Men's Work.

—This paper was read by Dr. WILLIAM H. LINK, of Petersburg, Ind. He said it was the tireless energy of originality and the endless application of original methods to both the expected and the unexpected in surgery that had thus far pushed our work and its underlying science toward perfection. By close and frequent observation defects in technique and improper application of surgical measures might be noted, and, having been recognized, avoided. There was no field in which object-lesson teaching was so effective, so fruitful of valuable practical results, as that of gynæcological surgery. The observer might not always know whether the operation he witnessed carried the patient on to recovery or the contrary; but, if he was a close observer, he was improving his own surgical judgment. He was studying and rejecting or adopting methods and aphorisms as they impressed his intelligence or his reason approved. By seeing work done under varying conditions and with different results one readily came to the conclusion that a private hospital was by no means necessary to successful work; that the pure air of a country or village home or of a clean room in a private residence in a city was as good for surgical work as that of the most painted and gilded hospital, and that no one need hesitate because his patient could not have the supposed advantages of some place specially set apart for the sick.

Intestinal Obstruction following Abdominal Section.—

Dr. L. H. DUNNING, of Indianapolis, read a paper thus entitled. Of the complications following abdominal section, he said, few were more fatal than occlusion of the intestines. It might ap-

pear in a few hours after the section or not until several weeks had elapsed. The author dealt with only acute intestinal obstruction. He remembered having met with but a single case in one hundred and thirty abdominal sections, and in this case the obstruction had occurred two weeks and a half after what he had considered a very successful ovariectomy. The question of the administration of cathartics in cases of suspected or threatened occlusion of the intestines was oftentimes one most difficult to decide. Under such circumstances he was inclined to the belief that during the first week after section cathartics were indicated, and he preferred to administer grain doses of calomel every hour for a few times, then two-drachm doses of Epsom salts every two hours until an action was obtained or it was demonstrated that a harmful effect was being produced. A distinct understanding of the pathological conditions that might be present must guide the operator in his search for the cause of the occlusion, and, when found, it should be dealt with in the shortest possible time consistent with the permanent cure of the patient.

The Present Status of the Treatment of Uterine Fibroids.—This paper was contributed by Dr. O. WEEDER, of Pittsburgh, and, in the absence of the author, was read by Dr. Thomas B. Eastman, of Indianapolis.

For the sake of convenience the author divided the treatment into the symptomatic and the radical, and confined himself to those views which seemed to be generally accepted by the leading and unbiased authorities of the present day. The principal symptoms produced by uterine fibroids that required attention were hemorrhage and pain. Hemorrhage was one of the most constant and dangerous complications, and was due to a diseased and hypertrophied condition of the uterine mucosa and hyperplasia of its blood-vessels (Wyder) or to hypertrophy of the uterine muscles accompanying the growth of the myoma with a simultaneous hyperplasia of the blood-vessels. The operations practiced for the radical cure of myomatous growths were vaginal enucleation, removal of the appendages, enucleation by laparotomy, and suprapubic hysterectomy. The author then considered these operations at length.

The Erect Posture for Gynæcological Examinations.—

This paper was contributed by Dr. WILLIAM B. DEWEES, of Salina, Kansas, but was read by John C. Sexton, of Rushville, Ind. Digital examination *per vaginam* with the patient in the erect posture afforded one of the most positive means of diagnosis in gynæcology. It was a well-established fact that respiration and the various movements and attitudes of the body, as well as pathological conditions, changed the conditions and environments of the viscera. Thus the importance of posturing the patient in making physical examinations in gynæcological practice became evident, as most of the symptoms of diseases of the intrapelvic organs were more marked, and very many only manifested, when the patient was standing; while certain conditions of descent, prolapse, or displacement might entirely disappear or change when the pressure or the superincumbent weight of the abdominal viscera was removed by the patient being placed in the dorsal, semiprone, genupectoral, or high pelvic posture. Therefore the erect posture was of paramount importance as an aid in diagnosis in this field of labor. The author emphasized the advantage and necessity of digital examination in the erect posture, more particularly in displacements of the uterus, vesical and rectal disorders, lack of perineal and vaginal support, ovarian and tubal disorders, abdominal and pelvic tumors, and abdominal tumors and pregnancy.

Tuberculosis of the Peritonæum, with Report of Cases.

—Dr. H. O. PANTZER, of Indianapolis, read a paper thus entitled. The author said that the prognosis and treatment of peri-

toneal tuberculosis had changed within the last decade. The accidental discovery of its curability by laparotomy had shifted its clinical relations. The author then quoted the conclusions of Dr. J. Whitridge Williams, from the *Johns Hopkins Hospital Reports*, 1892, on tuberculosis of the female generative organs. He reported a case of primary genital tuberculosis giving rise to a tubercular peritonitis and to tubercular disease of the abdominal parietes. Case II was one of primary genital tuberculosis following a puerperal sacculated ascites resembling an ovarian tumor. Laparotomy was performed and the patient recovered. Case III was one of genital tuberculosis complicated with suppurative infection and pelvic peritonitis. Laparotomy was done, and was followed by recovery of the patient.

This disease, from being regarded as a fatal and most intractable affection, belonging to the domain of internal medicine, had, since its accession to the realm of surgery, come to be regarded as quite submissive. A mistaken diagnosis had repeatedly led to the opening of the abdominal cavity. Instead of an ovarian tumor, an enlarged gall-bladder, a nephrosis, or some other legitimate object of surgical interest being found, tubercular disease of the peritonæum in some of its multiple forms presented itself. The abdomen was closed without any attempt at treatment, or at most the ascitic fluid was evacuated. It was noted that these cases did better afterward, and that some of the patients fully recovered. In 1884 Koenig had advocated laparotomy as a curative measure for peritoneal tuberculosis, and the operation had been done by other surgeons since.

The Treatment of Diseases of the Uterine Appendages.

—Dr. WILLIAM H. HUMISTON, of Cleveland, read a paper on this subject, in which he said the frequency and importance of diseases of the appendages were recognized by all practitioners of medicine. The early recognition of these diseases was of unusual importance, as by instituting proper treatment at once we could save a large percentage of the patients from a major operation and a prolonged convalescence. Simple inflammatory conditions of the tubes and ovaries, before extensive adhesions had taken place, could be treated successfully by rest, boroglyceride and iodine tampons, long-continued hot-water douches, and thorough curettement of the uterus, followed by a course of galvanism. He had cured a few cases where the ovaries were prolapsed and somewhat adherent by adding massage to the above-mentioned treatment. But, as a rule, if the case had been neglected until pelvic peritonitis had occurred, with its tendency to adhesions and recurrence, we should save many years of suffering, if not life itself, by advising removal of the appendages after a sufficient trial had been given to conservative treatment.

Frequently in the puerperal state there was a pelvic peritonitis without the tubes being affected, the inflammation spreading directly through the uterus; there was an exudate formed which rest and proper treatment would cause to be absorbed and leave the appendages healthy, so that afterward pregnancy might take place and the patient go on to full term. In these cases, if suppuration occurred, laparotomy should be advised. In tubercular salpingitis the question of removal would depend wholly upon the amount of general systemic infection. The author believed that nearly all suppurative diseases of the tubes and ovaries were due to gonorrhœa. It was his experience that had led him to this belief.

He closed with a few words on the value of electricity in the treatment of inflammations of the uterus and its appendages. He valued this very highly, and in the catarrhal forms of endometritis in young girls and primiparæ we could obtain a cure if sufficient time was given. He applied the positive pole within the uterus, and the negative, in the form of a broad electrode, over the whole abdominal region, using a current

strength of from twenty to fifty milliamperes for five minutes every third day. It required from fifteen to twenty applications to complete a cure.

(To be concluded.)

Book Notices.

Manuel du médecin praticien. La pratique dermatologique et syphiligraphique des hôpitaux de Paris. Aide-mémoire et formulaire. Par le Professeur PAUL LEFERT. Paris: J. B. Baillière et fils. 1893. Pp. vi-7 to 288.

This little book is a compilation of the modern methods of treatment of skin diseases by the dermatological specialists of the principal hospitals of Paris. Often under the title of a disease there is a description of the methods of treatment followed by several specialists. The list of diseases seems to be extensive and the formulæ sufficiently numerous to make the volume very useful to the physician.

Ein dermatologisches System auf pathologisch-anatomischer (Hebra'scher) Basis. Von Dr. S. JESSENER, Königsberg i. Pr. Hamburg und Leipsic: Leopold Voss, 1893. Pp. 66.

In this opusculum the author discusses the fundamental principles of a classification of skin diseases, presents a synopsis of the classifications of Tommasoli, Auspitz, and Hebra, and finally gives his own classification. In the latter he has six classes: First, functional anomalies; second, circulatory anomalies; third, inflammatory processes; fourth, hypertrophies; fifth, neoplasms; sixth, retrogressive nutritional disturbances. The ideal system of classification does not seem to us to have been discovered as yet.

BOOKS, ETC., RECEIVED.

Mirror Surgery and Bandaging, including the Treatment of Fractures and Dislocations, Tracheotomy, Intubation of the Larynx, Ligation of Arteries, and Amputations. By Henry R. Wharton, M.D., Demonstrator of Surgery and Lecturer on Surgical Diseases of Children in the University of Pennsylvania, etc. Second Edition, thoroughly revised and enlarged, with Four Hundred and Sixteen Illustrations. Philadelphia: Lea Brothers & Co., 1893. Pp. viii-13 to 529. [Price, \$8.]

Clinical Gynecology: being a Handbook of Diseases peculiar to Women. By Thomas Madden Moore, M.D., F.R.C.S. Ed., Obstetric Physician and Gynecologist, Mater Misericordiæ Hospital, Dublin, etc. With Two Hundred and Fifty-nine Illustrations. Philadelphia: J. B. Lippincott Company, 1893. Pp. xvi-11 to 562. [Price, \$4.]

Lectures and Essays on Fevers and Diphtheria, 1849 to 1879. By Sir William Jenner, Bart., G.C.B., M.D. Lond., and F.R.C.P. Oxon., LL.D. Cantab. and Edin., etc. New York: Macmillan & Co., 1893. Pp. xii-3 to 581. [Price \$4.]

Essentials of Minor Surgery, Bandaging, and Venereal Diseases. Arranged in the Form of Questions and Answers. Prepared especially for Students of Medicine. By Edward Martin, A.M., M.D., Clinical Professor of Genito-urinary Diseases in the University of Pennsylvania, etc. Second Edition, revised and enlarged. Seventy-eight Illustrations. Philadelphia: W. B. Saunders, 1893. [Price, \$1.] [Saunders's Question Compend, No. 12.]

Essentials of Bacteriology: being a Concise and Systematic Introduction to the Study of Micro-organisms for the Use of Students and Practitioners. By M. V. Ball, M.D., Physician

to the Eastern State Penitentiary at Philadelphia. Second Edition. With Eighty-one Illustrations, some in Colors, and Five Plates. Philadelphia: W. B. Saunders, 1893. [Price, \$1.] [*Saunders's Question Compend.*]

A Handbook of Ophthalmic Science and Practice. By Henry E. Juler, F. R. C. S., Ophthalmic Surgeon to St. Mary's Hospital; Surgeon to the Royal Westminster Ophthalmic Hospital, etc. With Illustrations. Second Edition. Philadelphia: Lea Brothers & Co., 1893. Pp. xvi-549.

Index-Catalogue of the Library of the Surgeon General's Office, United States Army. Authors and Subjects. Vol. XIV. Sutures—Universally. Washington: Government Printing Office, 1893. Pp. 14-1016.

Transactions of the Medical Association of Georgia. Forty-fourth Annual Session. 1893.

Medicación y Medicamentos Cardio-Motores. Por D. Antonio Espina y Capo, Médico, por oposición, del Hospital Provincial de Madrid. Segunda Edición, corregida y considerablemente aumentada. Madrid: Administración de la Revista de Medicina y Cirugía Prácticas, 1893. Pp. vi-7 to 334. [*Biblioteca Científica Moderna.*]

The Treatment of Pneumonia in St. Francis Hospital, with Results in Two Hundred and Twenty-eight Cases. By Arnot Spence, M. D., New York. [Reprinted from the *Medical Record.*]

Essential Details in the Conduct of Labor. By Kate Reynolds Lobingier, A. B., M. D., Denver, Col. (Read before the Colorado State Medical Society, 1893.)

Appendicitis. Clinical Lecture at the New York Post-graduate Medical School, February 11, 1893. By R. T. Morris, A. M., M. D., New York.

Hysterectomy by a New Method, which is Simple, Safe, Bloodless, and entirely obviates the Necessity of either Clamp, Cantery, or Ligature; a Major Operation converted into a Minor one by a Simple Process of Easy Dissection. By E. H. Pratt, M. D., LL. D., Chicago. [Reprinted from the *Journal of Official Surgery.*]

Continuation of Report on Hysterectomies. Nine more Cases of Hysterectomy performed by the New Method. By E. H. Pratt, M. D. [Reprinted from the *Journal of Official Surgery.*]

Results in Ninety Cases of Pulmonary Tuberculosis, treated at the Winyam Sanitarium at Asheville, N. C., from May 1, 1891, to May 1, 1892. With a Comparison of Results obtained with and without the Use of Tuberculin. By Karl von Ruck, M. D., Asheville, N. C. [Reprinted from the *Medical News.*]

Infectious Appendicitis. By Robert T. Morris, M. D., of New York.

Miscellany.

Some Therapeutic Problems awaiting Solution.—In an editorial article thus entitled the *Lancet* says:

Complaints are frequently made regarding the backwardness and slow progress of therapeutics. In view of the complexity of the phenomena which are involved, the wide range of individual idiosyncrasy, and the impossibility in many cases of instituting anything in the nature of exact experiment, it is possible that these complaints may be a little unreasonable. No one doubts that rapid and brilliant progress is continually being made in our knowledge of the pathology and the clinical history of disease, and when the conditions of the question are fairly considered it will not seem surprising that therapeutic progress

should follow rather than precede advances in pathology and clinical medicine. However this may be, it is desirable that we should from time to time review our position regarding some of the as yet unsolved or imperfectly solved problems of medicine. Time leaves little unchanged, and even in the absence of any notable experiments or discoveries it will always be found that we are from year to year insensibly altering our attitude toward the great therapeutic controversies of our age. Experience always teaches something, even if it be only caution and skepticism, and every day facts arise which tend either to confirm or to undermine provisional theories and working hypotheses. Truth prevails very slowly and error is as slowly expelled; but the intellectual atmosphere is ever changing. Doctrines that seemed to be probable a decade ago appear to be hardly worth contending against to-day. Theories that gave a passing satisfaction to the thoughtful physician of the last generation seem to be strangely outworn to-day, although little may have been accomplished in the way of tangible disproof.

We may find illustrations of our remarks in such diseases as syphilis, phthisis, pneumonia, diphtheria, and typhoid fever. It is not so long since the revolt against the abuse of mercury was in full swing and had gone so far that certain accomplished observers maintained that some of the worst features generally attributed to the disease were really due to the remedy. Now we feel that this question has passed out of the sphere of serious discussion. With a practical unanimity we acknowledge the value of mercury, and the only problems that await solution in this connection are the proper form of the drug to employ in a given case, the correct dosage, and the mode of administration. Phthisis affords a more difficult case. For the present, treatment by inoculation stands condemned, and it is not likely to be generally revived unless more extensive and authentic evidence of its utility than that which first gave it vogue is forthcoming. We have not, however, yet finally determined whether the antiseptic treatment of phthisis is as sound in practice as it seems to be plausible in theory. The use of antiseptic inhalations, though much less general than it was a few years ago, still holds its ground to some extent. We would commend to the profession the determination of the following question, which lies at the root of the problem: Supposing it be granted that bacilli are the cause of phthisis and that their destruction is the legitimate object of the efforts of the physician, is there any evidence to show that an antiseptic solution or vapor can reach the seat of the disease in sufficient strength to effect this object? We fear that, for the present at least, there is no such evidence; and without discouraging further experiment we very decidedly deprecate the use of inhalers and inhalations which are theoretically indefensible and manifestly ineffective. Then, again, with reference to the same disease, much advantage would arise from the diffusion of more definite views regarding the different effects of the various sanatoria upon its progress and palliation or cure. The high altitudes, the ocean voyage, and the desert air are all known to possess considerable efficacy, but although the literature of the subject is rapidly increasing, it can not be said that the profession generally has assimilated the opinions of experts on these subjects.

Pneumonia is still more or less of an opprobrium to the therapist. Vigorous stimulation still commands the approval of the great majority of adherents, but thoughtful physicians can hardly repress a doubt as to whether it is universally applicable and whether a place might not still be left for venesection and antimony. Sweeping generalizations in medicine are hardly ever true, and the time may come when greater therapeutic distinctions will be drawn between the different types of case, to the great advantage of the patients. Then

we need further to make up our minds whether cardiac failure is really the chief source of danger in pneumonia, and, if it be so, whether we have made sufficient use of our great cardiac tonic, digitalis.

It is not so long since one of the great battle grounds of practical medicine was the identity or non-identity of laryngeal diphtheria and membranous croup. This question has never been authoritatively settled, and although the doctrine of identity has tended to prevail, somehow or other the question has lost its interest, and we have come to see that its practical importance had been overrated. What is certain is the clinical fact that a membranous affection of the pharynx is only moderately perilous, while a membranous affection of the larynx is excessively dangerous, and in young children is very frequently fatal. In view of these clinical facts, the question of the precise pathological character of the membrane in the different cases becomes of minor interest. More important are the questions whether the removal or destruction of the membrane is ever advisable and when tracheotomy should be performed. The former question is now usually answered in the negative; and the latter raises one of the most difficult points in therapeutics, and one which is further rendered perplexing by the fact that foreign experience seems to be at variance with our own.

As regards the last disease on our list—viz., typhoid fever—we greatly need more authoritative teaching and more defined views on two questions: Firstly, Is intestinal antiseptics the legitimate aim of treatment, and, if so, which of the numerous antiseptics is the most suitable one? and, secondly, Is antipyresis generally advisable, and, if so, are we to trust to medicinal antipyretics or to the cold bath? To discuss these questions adequately would take us beyond our present limits, but we commend them to the thoughtful attention of our readers. We may merely suggest that intestinal antiseptics is still upon its trial, and that as regards antipyresis British practitioners have perhaps unduly neglected the external application of cold.

The Philadelphia Polyclinic.—It is announced that for the week beginning October 30th the subject of cataract will be considered with reference to its etiology, early recognition and management, prognosis, determination of maturity, operations for its removal, after-treatment, and adjustment of lenses. Traumatic, secondary, and juvenile cataracts will receive special consideration. Operations will be done and clinical studies will be carried on in the wards, operating rooms, and clinics of the Polyclinic, Wills Eye Hospital, and other hospitals with which the members of the teaching staff are connected. These hospitals in the aggregate contain upward of one hundred beds devoted to eye patients and have a dispensary service of twenty thousand new cases of diseases of the eye annually. Opportunity will be given members of the class to perform, under the supervision of the professors, the various cataract operations on the eyes of lower animals. There will be lectures and illustrated demonstrations of important points, and a series of conferences, conducted by the professors and participated in by the class, to consider questions now being discussed by the profession. The fee for the course will be fifteen dollars, and to students already taking the regular course on diseases of the eye, five dollars. Conferences will be held and, when not otherwise stated, clinics and demonstrations will be given, at the Polyclinic Hospital, Lombard Street, between Eighteenth and Nineteenth Streets. Monday, October 30th.—9 A. M.: Clinical Demonstrations, Dr. Thorington. 10 A. M.: The History of Cataract Operations, Dr. Schneideman. 2 P. M.: Clinic at Wills Eye Hospital, Dr. Risley. 4 P. Large Doses of Strychnine in the Treatment of Pulmonary and Cardiac Diseases.

—This was the title of a paper read by Dr. Thomas J. Mays, professor of diseases of the chest in the Philadelphia Polyclinic and visiting physician to the Rush Hospital for Consumption, before the Philadelphia County Medical Society, on September 27th. The paper was as follows:

From quite an extended experience with the use of strychnine I feel convinced that this drug gives better practical results in the treatment of pulmonary and cardiac diseases than any other single remedy at our command, and it occurred to me that a short discussion of the principles which I have followed in its administration might be of interest to the members of this society.

It is needless to tell you that strychnine has a more powerful stimulating influence over the nervous system than any other drug in the materia medica, and that, besides its general action, it has a special influence on the nerve supply of the lungs, heart, stomach, intestines, etc. Now, without going into details, it is my belief that many affections of the lungs and heart are fundamentally dependent on disorder of the nerves which supply these organs, and that the curative effects of this agent in these diseases rest largely on the power which it has in correcting this primary aberration. Over and above this it has been recently shown that strychnine also has the faculty of multiplying the corpuscular elements of the blood, and is therefore, like iron, a blood-builder. A combination of such valuable properties in a single agent makes it apparent, on theoretic grounds alone, why strychnine should possess such a beneficial therapeutic effect in the diseases which we are here considering, since anæmia is one of their most common compli-

cations. In spite of these desirable qualities, I believe that we often fail in obtaining its best effects by giving it in doses which are entirely too diminutive. I do not mean to say that strychnine should be given in large doses in every disease to which it is applicable, for such a statement might lead to great harm if it were practically carried to its legitimate end, but these remarks pertain only to those diseases to which reference is made in this paper. The custom of giving strychnine in doses of a sixtieth or a fiftieth of a grain I have discarded long ago, for I feel satisfied that such amounts are comparatively worthless. It is very rare that I begin with a smaller dose than a thirty-second of a grain, and more often with a thirtieth of a grain, and then gradually increase in an ascending scale until I touch the limit of toleration. Strychnine is peculiar in this respect. The length of the ascending scale from the effects of such a dose to a point where the physiological action of the drug begins to develop itself is usually very long, and during the time that this is traversed by the therapist a free opportunity is given in which to obtain the full stimulant action of the drug in gradually increased doses. I usually incorporate a grain of strychnine with phenacetin, quinine, etc., and divide the whole into thirty-two capsules, and give one capsule four times a day. This lasts eight days, and then an eighth of a grain more of strychnine is added to the whole quantity, which is thereafter increased a fourth of a grain every eighth day until the limit of toleration is approached. This varies very much in different individuals. I have a number of patients under my care at the present time who are taking a tenth of a grain, four who are taking a seventh of a grain, and one who is taking a sixth of a grain four times a day. Most of these patients have been taking the drug from three to seven months continuously. I have seen patients, however, who could not endure more than a twentieth of a grain four times a day. So soon as the patient begins to show evidence of intoxication the dose is reduced to a point where this is no longer manifested, and then maintained there permanently or again increased after some time. It is possible, however, and this should always be borne in mind, that the dose which was toxic once may in time be taken with impunity. This would seem to show that the poison line of strychnine recedes, and that the drug establishes a certain degree of tolerance for itself. Yet I have met with one case where the administration of the drug was broken off for almost two weeks, and then, on resuming the same dose which was previously taken, marked rigidity of the lower limbs followed after the first two doses.

What, if any, are the untoward effects of strychnine when given in such large doses? So far as I know, there are none except its occasional tendency to produce diarrhœa; but at the very worst I do not believe this proneness is very pronounced. In my earlier acquaintance with it I fancied that it aggravated the diarrhœa which is such a frequent accompaniment of phthisis, but my later experience fails to confirm this, since I have seen cases of intestinal tuberculosis get well when strychnine was given in combination with morphine and oxide of zinc. It has been asserted that it causes albuminuria by reason of the high blood tension which it brings about. Of this I have not observed the least evidence, having frequently examined the urine of patients to whom strychnine had been administered in such large doses for more than a year.

I will now briefly consider in greater detail the mode of giving strychnine in each disease to which it is believed to be applicable. In *asthma* I usually begin by introducing about a twentieth of a grain under the skin, and administer about a thirtieth or a twenty-fifth of a grain by the mouth four times a day, and gradually increase this in the way above indicated. Hypo-

dermically it is given once a day or every other day, and, if possible, in the evening, until there is an approach to the production of the toxic effects of the drug. Suitable doses of phenacetin, quinine, capsicum, and ammonium muriate will enhance its action. So far as my experience goes, strychnine must be regarded as the most powerful adjuvant in the treatment of asthma, although we must never lose sight of the importance of treating the diathesis or exciting cause on which the disease often rests, and also of improving the general nutrition.

Bronchitis, whether acute or chronic, is very much benefited by strychnine. It checks the cough, diminishes the expectoration, improves the appetite, and puts to one side the whole constitutional relaxation and feebleness frequently present, especially in the chronic form of this disease. It must be given in ascending doses, and may be combined with benefit with the syrup of the hypophosphites or hydriodic acid, or with both.

Strychnine is one of the most useful agents in treating acute pneumonia, whether this is of the croupous or catarrhal variety. I usually begin by injecting a twentieth of a grain, and if the case is severe I keep this up morning and evening, together with the internal administration of a twentieth of a grain every three or four hours until symptoms of intoxication begin to show themselves. This I have seen to take place on the second and third day of the disease. If the case is a mild one it will suffice to give a twentieth of a grain every four hours.

I know of no disease which is more eminently benefited by strychnine than pulmonary consumption. Indeed, as a rule, it seems that sufferers from this disease are capable of taking this drug in extraordinary large doses. I have a number of phthisical people under my care at the present time, both in hospital and in private practice, who are taking over half a grain of it a day—a dose which had been reached by a gradual increase of a smaller one. For a more complete description of the use of strychnine in primary pulmonary diseases I would refer you to a paper of mine on this subject, contained in the *Medical News* of July 22, 1893, and the remainder of this paper will be devoted to a consideration of the application of this drug to cardiac and cardio-pulmonic diseases.

In recommending strychnine as one of our most valuable cardiac stimulants a fear may spring up in the minds of many that this drug is put forward for the purpose of displacing digitalis—the old and well-tried heart tonic. That such a suspicion is not altogether groundless when held by those who prescribe digitalis for almost every phase and form of heart disease they meet is true; but he who looks the question of cardiac therapeutics squarely in the face, feels, although more perhaps from an instinctive than from a scientific standpoint, that the action of digitalis is not interchangeable with that of strychnine, and that each fulfills its own peculiar indication in the treatment of diseases of the heart. Although we may not be able to draw a rigid line of demarcation between the behavior of these two agents, we have experimental evidence to show that digitalis acts more on the muscular and less on the nervous structure of the heart than strychnine. My own experiments demonstrate that digitalis enhances or increases the irritability of the heart muscle, while strychnine depresses or reduces it; and that the former arrests the heart in systole while the latter arrests it in diastole. It is my belief that the action of these drugs is as dissimilar clinically as it has been shown to be physiologically, and that strychnine is principally indicated in those diseases of the heart which are dependent on a disturbance of innervation, as, for example, in simple cardiac weakness and in irregularity and intermittency of its pulsations, while digitalis is preferable in cases where there is a want of compensatory power in the heart muscle, as in valvular incompetency.

Bearing in mind this difference, strychnine should be prescribed when the nerve supply of the heart is enfeebled through auto-intoxication such as is found in the post-paralysis of diphtheria, scarlatina, measles, small-pox, influenza, whooping-cough, and in poisoning from alcohol, lead, mercury, etc.

Irregularity and intermittency of the heart's action are frequently benefited by the administration of large doses of strychnine, and more often than not do we find that digitalis is utterly useless in such cases. Sometimes the irregularity will remain even under the influence of strychnine, but the symptoms which are dependent on or are a part of this condition—such as pain in the precordium, orthopnoea, oppression of the chest—will improve or disappear, especially if suitable evacuant remedies are used at the same time. This whole disorder I regard as being probably due to a want of power in the discharge of nerve force of the heart, or rather, perhaps, to a lack of nerve control over the discharge of the muscle force of the heart. This weakness of nerve power is not only marked in the heart, but it is also apparent in the lungs and frequently manifests itself, especially in elderly people, in a coexistent œdema of the bases of both lungs.

Moreover, there is often found an irregularity or intermittency of the heart's action in severe seizures of asthma, and I know of nothing which will remove this accompaniment, as well as the original disease, as strychnine in large doses promptly administered, both hypodermically and by the mouth.

Angina pectoris is another paroxysmal disease in the treatment of which strychnine in large doses stands pre-eminent.

Again, digitalis is always regarded as the sovereign remedy in the treatment of valvular diseases of the heart and their sequences, but there comes a period in the life history of every such affection in which digitalis, no matter how much benefit was derived from it before, proves utterly useless. This leads, of course, to disappointment, and often gives rise to serious suspicion concerning the utility of this important agent. The fault lies, however, not in the drug, but in its improper application. It has done all that could be reasonably expected of it. It stimulated the heart muscle to renewed activity after the valvular rupture occurred. It aided in developing its muscular fibers and restored its former power; but now, for some reason or other, the nervous energy of the patient begins to flag, and the heart walls commence to relax in spite of the muscular hypertrophy which is present, and digitalis no longer possesses the spurring properties which it once had. The blood dams up in the left ventricle and auricle, the pulmonary circulation becomes impaired, œdema and congestion of the lungs follow, and death is threatened by way of the pulmonary organs. It is at such a time, when digitalis fails to counteract these many incidental complications, that strychnine steps in and shows its superior value as a tonic to the waning nerve energy of the heart and lungs.

In the discussion, Dr. Lawrence F. Flick said: This is too practical a subject to be permitted to pass without some discussion. There is no drug that has become more popular in recent years than has strychnine just in the class of cases to which Dr. Mays alludes. While we have apparently empirically come to the conclusion that this drug is of very great value in these diseases, I do not know that I have seen a satisfactory explanation of why it is so. There is one peculiar result in the use of strychnine which gives somewhat of a clue to its manner of action. This was not mentioned by Dr. Mays. It is the marked increase of weight that occurs under the use of large doses of strychnine. I do not know of any other drug which will produce this effect so rapidly and so satisfactorily. It seems to me to indicate that the real cause of benefit, after all, is possibly the increase of nutrition, and yet why this increase

in nutrition from the use of strychnine? It is probable that its effect in stimulating involuntary muscles has a great deal to do with the result. The special action of strychnine is stimulation of involuntary muscles. This is true not only of the muscles of the heart and of the blood-vessels, but also of the muscles of the stomach, intestines, etc.

In the treatment of tuberculosis strychnine is certainly one of the most valuable remedies that we possess. It should be used in large doses. It along with many other remedies which go to build up the nervous system and improve the nutrition are really essential in the treatment of tuberculosis. When we use remedies which build up the nervous system, and with them use the germicides that have lately been introduced, we can obtain very gratifying results in the treatment of this disease which has hitherto been so discouraging. The use of strychnine and other stimulating drugs should be accompanied by the employment of such germicides as have shown themselves to be of value. I have seen recently reports of some excellent results with tuberculin and tuberculinidin, and if these reports continue to come as they have, I feel that we can soon approach the treatment of tuberculosis with a great deal more courage than in the past.

Dr. Charles Wirgman said: I can give my testimony as to the value of strychnine in asthma. I have a patient suffering with severe asthma, the result of hay fever, taking one twelfth of a grain four times a day. He is a man of relaxed muscular fiber and rather feeble constitution. He has had these attacks every autumn for some years. I began with one sixtieth of a grain, and increased to one fortieth and then to one thirtieth. Observing no toxic symptoms, I increased the dose to one twentieth, and finally to one twelfth, four times a day, I think with decided benefit to the general nervous tone. I have never observed in this case or in others any accumulative effect of the drug. As far as its influence upon the pulmonary tract is concerned, I have observed no positive action—that is, in the sense of an expectorant—but it certainly does increase the general tone so that a patient has more strength to expel the secretion which accumulates. The only symptom that might indicate a toxic action has been a slight amount of spinal irritation, but I have been inclined to attribute this to the semi-recumbent position which he has been compelled to maintain.

Dr. S. Solis-Cohen said: There is no question in my mind that large doses of strychnine can in certain cases be well borne for prolonged periods. In hysterical and other forms of aphonia, and in paralysis following diphtheria, I have frequently given as much as a fifth of a grain three times a day for several days in succession, having reached this dose by gradual increment; and I have now under my care a man who has been taking a tenth of a grain of strychnine three times a day for some two years, and who has at times for short periods taken even larger doses. This is a case of syringomyelia with cardiac feebleness. But while I am sure, from what Dr. Mays and others have reported, and from my own observations extending over many years, that these doses of strychnine can be well borne and are useful in certain selected cases, I am not one of those who believe that these large doses should be given to every case or to a large number of cases. Both in acute cases and when the drug is to be long continued, I have seen, as a rule, better results from what nowadays would be considered very small doses—namely, about one sixty-fourth of a grain or one milligramme. The reason for that, I think, is quite clear. In some very interesting researches communicated by Mr. Hodges to the American Physiological Association at the last meeting of the Congress of Physicians and Surgeons at Washington, and in which the effects of exercise and rest upon the ganglion cells of the brains of bees and of sparrows were

demonstrated, it was shown that during the periods of activity a certain vacuolation of the gray matter of the nerve cells was produced; an absolute destruction of tissue during the physiological process of nervous function. During the period of rest, repair takes place. Strychnine is an agent which above all others stimulates nervous function, and naturally in the process of stimulation of nervous function leads to destruction of nerve tissue. This is, of course, the absolute physical necessity; energy can only be produced, whether in the body or out of it, by an arrangement of matter—a reduction of existing forms into less complex forms, with liberation of the energy locked up in the complexity of structure. Mr. Hodges also showed some spinal cells from a cat poisoned with strychnine, and called attention to the correspondence between the vacuolation in the spinal cells of the cat from strychnine activity and the vacuolation in the brain cells of bees and sparrows from normal activity; there is no doubt in my mind that the correspondence holds throughout. Strychnine adds nothing to the stores of energy of the patient. Its great usefulness in apparently giving strength to a weak man is due to the fact that it calls upon him for the exercise to the full of such reserve energy as he possesses. It stimulates the nerve cells to their highest activity, quickly liberating the locked-up energy, and in so stimulating it inevitably uses up a certain amount of nerve tissue. If, after this, sufficient rest is allowed, repair takes place, and takes place more quickly because the nutritive processes have been stimulated by the action of the drug. Now, if the amount of activity with concomitant reduction of nerve tissue caused by strychnine can be proportioned to the needs of the patient so nicely that we shall get the maximum of stimulation of the nutritional processes and the minimum of expenditure of the patient's nerve tissue, it is evident that this is the proper point at which to stop. Pushing it beyond that, we cause an unnecessary expenditure of energy and loss of tissue which has to be made up from the food and in other ways. The nicety of adjustment most beneficial is not to be expressed in figures; it differs with the patient and with the disease, and to reach it requires careful observation and good judgment. Still it is something that we should aim at and that every intelligent physician should be able to secure. The fact that we do not kill a patient by large doses of strychnine does not necessarily prove that we have done him good. The fact that a patient is not killed by a surgical operation does not prove that the operation was indicated in that particular case. It may have been or it may not. Dr. Mays has alluded to the tolerance finally produced to large doses of strychnine. In this lies, I think, the patient's safety. The nerve cells become habituated to it, and refuse to respond up to a certain point. It is the small excess beyond this point that is over the amount tolerated to which the therapeutic effect is due.

In the treatment of acute pneumonia, strychnine is unquestionably one of the best agents that we possess, given in proper doses. I have had occasion to observe at the Philadelphia Hospital, in patients side by side, the comparative effect of small and large doses, and while admitting all the difficulties in the way of drawing conclusions from such comparisons, I am sure that the patients with small doses did at least as well as those who received large doses. I am not afraid to push strychnine up to half a grain, if necessary, and when the indication for such dosage exists. In Dr. Mays's cases I have no doubt that large doses were indicated, but in less skillful hands than Dr. Mays I am sure the routine use of large doses might do harm, not by producing immediate death, but by gradually exhausting the nervous energy of the patient.

In acute cases the best method of administration of strychnine is by means of dosimetric granules. I use the word "dosi-

metric," not that there is anything magical in the term, but that it indicates the manner in which the granules are prepared. Strychnine arseniate in doses of half a milligramme ($\frac{1}{100}$ grain) can be given and repeated every fifteen minutes or half an hour until the desired physiological or therapeutic effect is produced. The administration can then be stopped, and, as the effect is often prolonged, need not be repeated until the next day. In some cases the nurse can be instructed to administer three or four granules—one granule at a time—at intervals of half an hour, and then none for three or four hours. Sometimes, after a patient has thus been given four granules ($\frac{2}{5}$ grain), the effect can then be kept up by a single granule twice or three times a day. As I have elsewhere published my views concerning the important place of strychnine in the treatment of affections of the heart, I will not now dilate further upon it.

To repeat what I more particularly desire to contribute to the present discussion, I believe that while strychnine is very useful in all the conditions described by Dr. Mays, the best effect can be obtained by limiting the dose to the smallest quantity that will produce the physiological reaction intended.

Dr. Mays said: I do not know that I have much to say in conclusion. The remarks made by Dr. Flick with reference to the influence of strychnine on nutrition are very apropos. The reason that I did not allude to this was because I have discussed this part of the subject in the paper to which I referred. It is quite evident to my mind that Dr. Flick has had a plentiful experience with the use of large doses of strychnine, because, among other things, he notes the influence of this drug upon nutrition. This action is certainly remarkable. I have so often observed this gain in weight that it is a common thing for me to expect the patient to gain in weight if he gets strychnine in ordinarily large doses, such as I have spoken of. I do not know whether Dr. Flick is correct in saying that it acts upon the involuntary muscles of the body, or whether it acts upon the trophic nerves. However, there is strong evidence for believing that strychnine affects the trophic or nutritive nerves of the body and stimulates them, and in this way improves nutrition. I have seen remarkable gain in weight in experimental cases in which nothing was given but strychnine hypodermically for a number of days. There was nearly always decided gain in weight in the cases that I have observed. I gave it in large doses.

In regard to the cumulative effect, I do not think that I have any observations in regard to the accumulation of the drug in the system. While I believe that strychnine acts like drugs that do accumulate in the system—such as atropine, digitalis, and strophanthus—yet there is a marked difference between the action of strychnine and the drugs mentioned. Strychnine does not have the profound effect upon the circulation that the other drugs have. We know that the cumulative effect of digitalis is due to the fact that elimination is checked.

I am sorry that I can not agree with Dr. Cohen in regard to the benefit of small doses in many diseases, although I believe that some diseases are more easily influenced by strychnine than are others. I believe, however, that pulmonary and cardiac diseases, such as were only referred to in my paper, are less easily influenced by strychnine than are many others. It is especially so in asthma, angina pectoris, and the other pulmonary and cardiac diseases to which I have referred, for in them it is perfectly useless to give small doses with the idea of cure. You might as well turn a garden hose on a Chicago fire as to expect to do much good with small doses in these diseases. I have tried small doses without any benefit.

In regard to the destructive action to which Dr. Cohen has referred, I can hardly believe that strychnine in ordinary physiological doses can have a destructive influence upon the nervous

system, although I can see how a large and poisonous dose could have such influence upon the nervous system. Indeed, we well know that atropine, digitalis, alcohol, and many other drugs, in common with strychnine, have such a disintegrating effect in toxic doses; but to say that in stimulant doses they have the same or even a similar effect is very far from the mark. It seems to me to be a confounding of the physiological with the pathological effects of a drug. Although I administer strychnine in large doses, I always remain within the sphere of its stimulant action. In fact, I fail to conceive how any drug which improves the nutritive state of the body can at the same time have a destructive influence on any tissue, except in so far as it may enhance the physiological waste of the body, which in turn is compensated by an increase in its physiological repair.

The Alvarenga Prize of the College of Physicians of Philadelphia.—It is announced that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, amounting to about a hundred and eighty dollars, will be made on July 14, 1894, provided that an essay deemed by the committee of award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but can not have been published, and must be received by the secretary of the college, Dr. Charles W. Dulles, Philadelphia, on or before May 1, 1894. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within it the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award.

The End of a Groundless Libel Suit.—At a meeting of the Philadelphia County Medical Society, held October 18, 1893, the following preamble and resolutions were unanimously adopted:

Whereas, Dr. James E. Reeves, of Chattanooga, Tenn., having denounced the so-called "Amick Cure" for consumption as a quack nostrum, and stated that its proprietor was not a physician in good and regular standing, was accused of criminal libel; and

Whereas, The grand jury has ignored the indictment brought against him, be it

Resolved, That the Philadelphia County Medical Society congratulates Dr. Reeves on his bravery—a bravery unfortunately too rare at the present day—and tenders him sympathy in the persecution to which he has been subjected;

Resolved, That no person who makes, deals in, or advertises as a cure a quack nostrum—that is to say, a preparation the composition of which is kept secret—can be termed a physician in good and regular standing, because such action is *ipso facto* sufficient to work forfeiture of membership in this or any other county medical society governed by the laws of the American Medical Association;

Resolved, That a copy of these resolutions, duly attested with the signatures of the president and secretary and with the seal of the society, be forwarded to Dr. Reeves, and that they be handed to the press for publication.

[Signed.] } DE FOREST WILLARD, *President*.
 } F. B. SCHNEIDEMAN, *Secretary*.

The Canadian Medical Association.—The officers for 1893-'94 are as follows: President, Dr. T. T. S. Harrison, of Selkirk, Ont.; vice-presidents, for Ontario, Dr. F. R. Eccles, of London, for Quebec, Dr. J. Stewart, of Montreal, for New

Brunswick, Dr. J. Christie, of St. John, for Nova Scotia, Dr. W. S. Muir, of Truro, for Manitoba, Dr. R. Spencer, of Brandon, for the Northwest Territories, Dr. F. H. Mewburn, of Lethbridge, for Prince Edward Island, Dr. F. B. Taylor, of Charlottetown, for British Columbia, Dr. R. E. McKeechie, of Nanaimo; general secretary, Dr. F. N. G. Starr, of Toronto; local secretaries, for Ontario, Dr. I. Olmsted, of Hamilton, for Quebec, Dr. J. V. Anglin, of Montreal, for New Brunswick, Dr. M. McLaren, of St. John, for Nova Scotia, Dr. R. A. H. McKeen, of Cow Bay, for Manitoba, Dr. A. McDiarmid, of Winnipeg, for the Northwest Territories, Dr. Calder, of Medicine Hat, for Prince Edward Island, Dr. Johnston, of Charlottetown, for British Columbia, Dr. Walker, of New Westminster; treasurer, Dr. H. B. Small, of Ottawa. The place of meeting in 1894 is St. John, N. B.

Some Practical Post-mortem Points.—At a meeting of the Philadelphia County Medical Society held on October 25th Dr. Henry W. Cattell, demonstrator of morbid anatomy in the University of Pennsylvania, read the following paper:

1. Get all the anatomical knowledge you can out of every autopsy you make. It is therefore usually advisable, especially in the case of females, to perform a preliminary laparotomy. Many surgical operations can be practiced upon the body without disfigurement—such as Alexander's operation, oophorectomy, removal of the ear ossicles and vermiform appendix, stretching of the sciatic nerve, symphysectomy, etc.

2. Do not forget to dictate the post-mortem notes while the autopsy is in progress.

3. Respect the feelings of the friends in every possible manner, and always return everything in a private house to its proper place. Be sure to leave no blood marks behind.

4. Be sure you have a legal right to make the post-mortem before you begin. The nearest relative, or the one who is going to pay the expenses of the funeral, should give the consent in writing.

5. Do not take away more tissue from a post-mortem than you are able to thoroughly work up.

6. Try to encourage a demand among the laity for the performance of autopsies.

7. In making an autopsy have a regular method for its performance, which is only to be modified by exceptional circumstances. Finish the examination of each organ in as thorough a manner as possible before the examination of another organ is commenced.

8. Label all your specimens at once with name of person from whom the specimen is removed, character of the specimen and relations in the body, date, and preservative fluid employed.

9. If you are so unfortunate as to cut yourself, wash the wound with running water for four or five minutes, and then dress antiseptically. Do not, out of bravado, go on with the post-mortem if there is any one else present who can complete it.

10. If you are not making the autopsy yourself, do not be too forward in making suggestions to the one who is making it but always be ready to do anything that you are asked to do in connection with the autopsy.

11. Let your medical friends enjoy the autopsy and specimens with you.

12. Get all the post-mortems you can; never refuse to make an autopsy for another, when you possibly can.

13. Tact will get you many autopsies; curiosity of relatives and friends can often be worked upon to get permission for an autopsy.

14. As the object of the autopsy is usually to find out the

cause of death, either for legal or scientific purposes, the post-mortem should, therefore, be conducted in as thorough and accurate a manner as possible.

15. In legal cases be sure to protect yourself in every possible way. The jars (which should never have been used) containing the specimens should be sealed in the presence of a witness. In important cases here in Philadelphia the coroner has both of his physicians present at the autopsy, so that the testimony is stronger; and in case of absence of one of the physicians the other can go on the witness stand and the case not be postponed.

16. If you value your peace of mind do not put yourself forward as an expert witness in medico-legal matters. Knowledge which you already have should be freely given to the court in criminal cases, but the court can not compel you to obtain expert knowledge without your consent.

17. In Germany the legal evidence of a post-mortem held by gaslight has been judged by the court, except under certain peculiar circumstances, to be void.

18. If two persons are lifting the body the lightest weight is at the feet.

19. Chloroform, when placed on a towel and the head enveloped in the towel, will quickly dispose of pediculi capitis.

20. Many signs of inflammation, especially of the mucous membrane, disappear after death. Remember that red flannel often colors the skin red.

21. Make the undertaker your friend. Do not recommend an undertaker who disapproves of post-mortems.

22. It is a good knife that will keep its edge in more than one post-mortem.

23. Do not jump at conclusions too quickly. Tentative diagnoses alone should be made until the post-mortem is complete.

24. Always weigh the important organs, and have some method by which you can tell the right from the left organ in case of the double ones. One nick in the left-sided organs and two in the right will readily distinguish them.

25. Wash your hands frequently during the performance of an autopsy, so as not to allow the blood to dry on the skin.

26. In opening a cystic kidney be careful that the liquid does not injure the eyes or soil the linen, as when the kidney is opened the liquid in the cyst is under pressure and may squirt several feet.

27. A duct can often be easily followed by making a nick in it, and then introducing a piece of broom stick or a groove director in the direction you desire to dissect. This is especially useful in the ureters and the ductus choledochus communis.

28. In writing the account of an autopsy describe what you see; do not use names of diseased conditions. These should be put in under the head of pathological diagnoses.

29. Urine or aromatic spirits of ammonia will best take off the odor from your hands. This odor is usually got from opening the intestines.

30. Ammonia (also the aromatic spirits) will remove iodine stains; a weak solution of the hypobromite solution will remove carbo-fuchsin and other aniline stains from the hands.

31. Any organ which you desire to save should be placed in a safe place so that it will not be returned to the body and sewed up.

32. The dissecting-room is a poor place to study pathology, on account of the chloride of zinc forming with albumin an insoluble albuminate of zinc.

33. Nervous tissue for microscopic study should not be placed in zinc chloride or in alcohol.

34. Remember that a post-mortem, with the exception of the brain and cord, can be made with a penknife.

35. Remember that the thoracic and abdominal organs can be removed by the rectum or the vagina.

36. Before removing the calvaria have a basin so placed that it will receive the blood and cerebro-spinal fluid.

37. Drawings, photographs, casts, cultures of micro-organisms, and microscopic slides are valuable additions to a well-written account of an autopsy.

38. A lesion in one part of the body will often suggest a careful search for a lesion in another part of the body.

39. Do not mistake the normal for the abnormal.

40. Squeezing the gall-bladder after the duodenum has been laid open will often cause bile to pass out, and the papilla, the ending of the common bile duct, can thus be demonstrated.

41. Remember that frozen sections of fresh tissue can be cut and mounted in a half hour to an hour.

42. Three hours is none too long in which to make a complete autopsy.

43. Be careful that the first rib does not scratch your hands when removing the tissues in that region. Therefore cover over the cut ends of the clavicle and ribs with the skin flaps.

44. Blood makes a good glue for affixing labels, and the blood of a person who has died from hydrocyanic poisoning makes a most excellent red ink which will keep for years without the addition of any preservative fluid.

45. Remember that after the brain has been removed the fundus of the eyes can be removed by a circular incision posteriorly, without disfigurement. The inside should then be stuffed with dark-colored wool or cloth.

46. In private cases you will be frequently judged of as to your skill as a pathologist by the neatness with which you sew up the body.

47. If you discover suspicious lesions, always stop the post-mortem and report the case at once to the coroner.

48. Remember in warm weather that the intestines are especially liable to undergo rapid decomposition when exposed to the air.

49. Remember that a railway train or cart may pass over the body and there be no abrasion in the skin more than a brush burn.

50. Remember that the color of organs is frequently changed when exposed to the air by the oxidation of the hæmoglobin. Also that the sulphide of iron frequently discolours organs after death, due to the sulphureted hydrogen during decomposition precipitating the Fe of the hæmoglobin.

51. The clavicle can be grasped and moved and the clavicular-sternal articulation thus readily discovered.

52. In removing the cord the following method may be used without disfigurement to the skin of the back part of the neck: Make a circular incision from the middle of the trapezius muscle of the one side to the middle of the same muscle of the other side, using as the center of the circle the external occipital protuberance. This will take you in the median line to about the second dorsal vertebra; then dissect away the skin with the muscles attached, and elevate this flap with a tenaculum and draw the shoulders backward. A sufficient amount of space will be given to then remove the cord in the usual manner.

53. If the rectus muscle on each side is cut near its origin, in the direction of Poupart's ligament, the abdominal cavity will be much more thoroughly exposed to view than in the ordinary manner. First, however, examine with the finger for hernia.

54. And lastly be honest. Every one diagnosticates lesions during life which are not found at the post-mortem. Even after a most careful post-mortem it is often impossible to tell from what the patient died.

Original Communications.

SOME REMARKS ON THE
STRUCTURE OF ŒDEMATOUS NASAL POLYPI.*

By JONATHAN WRIGHT, M. D.

THE material upon which the following observations were made was obtained from about one hundred and fifty individuals. A few were normal cases; the others were suffering from various pathological conditions of the upper air passages. About twenty-five of these cases furnished the nasal polypi. All the polypi were removed during life. As nearly all were multiple, the number of separate polypi examined must certainly have been more than fifty, but I have no definite record of that point.

This material was prepared for histological examination principally by hardening in alcohol, imbedding in celloidin, and double staining with hæmatoxylin and eosin. Other methods of hardening and staining were also used for comparison.

It is a matter of great regret to me that no material could be obtained by post-mortem section of the nasal cavities. Operations *intra vitam* can never be depended on to furnish the true base of these growths. For this reason alone Zuckerkandl's examinations as described in his last volume † would be of great value.

Epithelium.—From its distribution in the body one can not help drawing the inference that the pavement epithelium is the form chosen by Nature to protect surfaces subjected to friction or irritation of various kinds. Haycraft and Carlier ‡ found ciliated cylindrical epithelium in the trachea of a fetal kitten. After birth the cilia are lost and the cylindrical epithelium gradually takes on a squamous type according to its exposure to friction.

Normally the epithelial lining of the nasal mucous membrane is cylindrical, ciliated below and smooth above the middle turbinated. Cylindrical epithelium, occasionally ciliated, is the variety that usually covers Œdematous polypi. Careful microscopical examinations by several other observers have shown places in these polypi where the cylindrical type is changing or has changed into the squamous. This change was first noted in that part of a nasal polypus which projected from the nose, and was the most exposed to irritation from the action of the air and the friction from without. Subsequently the same alteration has been noted deep in the nose and supposed to be due to the chafing of the polyp at that point against contiguous parts. While this change has been described and figured by several competent and trustworthy observers, it has never been my fortune to see it in typical gelatinous polypi.

I have, however, repeatedly observed it in those growths

where œdema was not a prominent feature. I have seen it so pronounced in a sarcoma of the middle turbinated that from the fragments removed at one time I thought the growth was an epithelioma.

The sections from which the drawings in Fig. 1 have been taken are not from a typical œdematous polypus. It

FIG. 1 (a).

is an advanced condition of chronic inflammation of the mucous membrane of the middle turbinated bone in which there are a few areas of œdema. The patient was suffering from empyema of the antrum of long standing. The source of the irritation was evidently not friction of one

FIG. 1 (b).

surface on the other, but the action of the ichorous purulent discharge from the antrum and its formation into crusts. The change to the squamous type in atrophic rhinitis may be regarded as an analogous process.

* Read before the American Laryngological Association at its fifteenth annual congress.

† Zuckerkandl. *Normale und pathologische Anatomie der Nasenhöhle, etc.*, II. Band, 1892.

‡ Haycraft and Carlier. *Journal of Microscopical Science*, vol. xxx, part 4.

Where this change in type takes place in the epithelium you will always notice the increase in the thickness of the layers. Often this thickening or proliferation takes a somewhat symmetrical form, making a scalloped fringe, as seen in the low-power drawing (a). Examined with the high power (b), it looks as though this proliferation must have started at the center of each scallop from one or two cells. With one twelfth oil immersion the spinous processes of the pavement cell may be seen (c). A moderately careful

FIG. 1 (c).

examination of these sections shows a gradual change, from one end of the specimen to the other, of the columnar to the squamous form of cell. The flat cell, however, rarely if ever in this metamorphosis in the nose reaches the dimensions seen in the skin. Although the proliferation of cylindrical cells into the form of digitations and papillae has been mentioned, I have never seen it. When this proliferation becomes very marked a change of type is always observed in my experience. There are nearly always found places on the surface of these polypi where the epithelial layer is thicker than others and thicker than normal; but where it takes this scalloped form the cells are atypical.

Stroma.—This may best be studied by comparing sections prepared in several different ways, as one method brings out some features at the expense of others.*

Coagulation of the fibrin in the serum which infiltrates the stroma renders differentiation of the connective tissue from it necessary for its study.

When this is accomplished, by means of staining or otherwise, it will be seen that we have as a framework for the mass a network of areolar tissue the size of whose

meshes is determined by the amount of serous infiltration. Where the latter is slight we have a firm, where abundant a soft, yielding mass; upon this also depends its degree of translucency. These meshes, usually long spindle shaped, are filled with fibrin coagulated into granular material, and threads, cobweb in their fineness under a high power. Sometimes the individual fibers of the fibrous tissue are separated one from another, and with the Weigert stain may be seen, in faintly yellow wavy outlines, the interstices filled with violet fibrin. Usually, however, the fibrous tissue is split up into strands of many fibers. There is no homogeneous groundwork taking a deep blue stain with hæmatoxylin, and dotted with branching eosin-stained cells, as in typical myxomata.

Oedema.—As a matter of fact, we have all degrees of this serous infiltration, so slight as to be only recognizable under the microscope in small areas up to the gelatinous state, where, if the fluid is squeezed out of the growth, very little is left.

The posterior ends of the inferior turbinated bodies and the swellings of the mucous membrane on each side of the posterior border of the septum often have in the rhinoscopic mirror a "water-logged look," and when removed with the cold snare would seem translucent if they were not so gorged with blood. Histologically they show no difference from the typical oedematous polypus except as to the degree of serous infiltration. The microscope reveals in one case a condition that is recognizable to the naked eye in the other. Why the typical oedematous polypus occurs more frequently in the upper part of the external wall of the nasal cavity is still a matter of conjecture, not of demonstration.

The oedema is always more marked at the most dependent parts of the growth, whether pedunculated or broad based, but I have never seen it penetrate the epithelial layer, although this has been described, and it has been said that rupture of the epithelial layer has taken place spontaneously so that the serum drained away. It may be doubted if the watery discharges from the nostrils, that are so frequently a distressing symptom in these cases, come as a rule directly from the water-logged tissues. It is probably always due to the irritation of the growth on the surrounding mucous membrane. Osmosis on wet days is evidently, as the law of physics would teach us, from without inward. The serum, containing not only salts in solution but large quantities of mucin, probably does not exude at all or but slightly. Even under the pressure exerted by the snare the external envelope of these growths usually remains intact except in the case of cysts near the surface.

That the elasticity of the tissues exerts considerable pressure on the fluid which they contain may easily be demonstrated by incising a large polyp after it has been removed, laying it on a clean white plate, and noticing the shrinking that takes place in its size, some of the fluid being rapidly squeezed out. This is particularly striking in the oedematous posterior ends of the inferior turbinated bodies referred to above. The more "gelatinous" the growth, the less resiliency it seems to have. The origin of the fluid is, of course, from the blood-vessels, but what the

* I have prepared sections as follows:

1. Hardening in alcohol; imbedding in celloidin; unstained and stained with hæmatoxylin and eosin.
2. Preliminary hardening in Müller's fluid, stained and unstained.
3. Weigert's fibrin stain.
4. Mounting unstained sections in glycerin with a little acetic acid.
5. Washing out the celloidin with ether and treated as above.
6. Washing out the mucin with baryta water.

mechanism of its production may be a matter of speculation and a problem to be left to the general pathologist. It is not a passive oedema. I have never heard of oedema of the mucous membrane of the nose in general anasarca, though it occurs about the soft palate and glottis. Clinical observation and histological study suggest that it is caused in some way by an antecedent chronic inflammation of the nasal mucous membrane. It may be supposed, first, that this has caused some diminution in the resiliency of the tissues which normally offer an elastic support to the blood-vessels; second, that occlusion of the blood-vessels occurs at some points, since thickening of their walls may be demonstrated in many sections, or they may be occluded by pressure of surrounding distorted tissues. Paralysis of the vaso-motor nerves is a matter of pure speculation.

The fluid contains serum albumin, which can be demonstrated in the undiluted state by the usual tests, though apparently it is not nearly so abundant as in pleural or abdominal effusions. It contains large quantities of mucin, which may be extracted from the tissues by cutting the polyp in small pieces and allowing them to soak for several hours in baryta water. Heat produces no perceptible change in the resultant fluid. Acetic acid, however, throws down an abundant thick precipitate. Alcohol also produces a slight precipitate. This richness in mucin has been adduced as a proof that these tumors are true myxomata. Mucin is the abundant constituent of the secretions of the normal as well as the abnormal mucous membranes. Mucin has also been demonstrated in inflammation of the connective tissue. It is the product of many varieties of cells. Occurring in the fluid of a nasal polypus neither proves nor disproves its myxomatous nature.

FIG. 2.

Round Cells.—The exudation of small round cells from the blood-vessels and the production of young connective tissue around them may be seen in Fig. 2.

These areas, as you will observe, bear some resemblance

to small round-celled sarcomatous tissue. This is the only histological suggestion I have ever seen of the reported malignant transformations of these growths. While such so called transformation may occur, just as sarcoma may appear in previously normal tissue, it is probable that the idea of its frequency arises from mistaking the character of the growth in its origin. Again, we meet in nasal pathological histology the difficulty, to which I have on several occasions drawn attention, of differentiating between granulation tissue, lymphoid hypertrophy, and small round-celled sarcoma. In this section the origin of the area is evident, but when in the section of these areas the lumen of the blood-vessel does not happen to be included, the resemblance to sarcoma is marked. In the same drawing you will notice at some distance from the blood-vessels round lymph cells of considerably large diameter, few in number, more widely separated one from another, and entangled in the fibers of the areolar tissue, the spaces of which are dilated and filled with granular fibrin. The ordinary hardening in alcohol and double staining does not reveal the branching cells of the connective tissue. Unstained and mounted in glycerin with a little acetic acid, the sections show them. A few cells may be seen in the connective tissue treated in this manner which resemble endothelial cells, but it is difficult to say whether these are derived, as some maintain, from the walls of the lymphatics, or are really altered connective-tissue cells. Any further evidence that the areolar spaces are really dilated lymph channels I have not been able to observe.

The exudation of small round cells into the stroma is frequently very marked. With the ordinary double staining the presence of one of these round cells in a dilated areolar space frequently gives the appearance of a large flat epithelial cell, the small cell serving as a nucleus and the walls of the areolar space serving as the edge of the cell. A very little study, however, easily shows its true nature.

Glands.—Billroth* first described nasal polypi more than thirty-five years ago as being made up principally of glandular tissue. In his *Surgical Pathology* in 1882 he says: "The majority of the mucous polypi of the nose . . . consists mostly of distorted and also of newly formed mucous glands whose closed ends are dilated occasionally to mucous cysts." This statement has been repeated by a few and contradicted by many. In my experience oedematous nasal polypi always contain fewer glands by far than the normal tissue. I presume true adenoma does occur in the nose. I have never seen one and I have never read a description of one which did not correspond fairly well with ordinary hypertrophy in which the glands had not for some reason undergone the degeneration usually seen in them from such chronic inflammatory changes. There is great discrepancy in the statements as regards the frequency of gland tissue in nasal polypi. It seems to me that this difference of opinion has arisen from the fact that the majority of observers have examined only those polypi removed during life with the snare, while others have ex-

* I have not been able to obtain a copy of Billroth's original paper—*Ueber den Bau der Schleimpolypen*, Berlin, 1855—but my information in regard to it is derived from quotations, frequently unreliable.

amined those taken post mortem from heads laid open by a longitudinal section. Now, the serous infiltration being always most abundant at the most dependent part, the more marked it is, the less there is seen in the section of the normal parts of the mucous membrane—*i. e.*, the glands, blood-vessels, etc. The budding or protrusion of what is to be a pedunculated polyp begins at some weak or more diseased spot of the mucous membrane, and, push-

disorganized gland by the proliferation of the fibrous tissue of stroma around it. Sometimes fibrous nodules are seen which are apparently the ultimate results of this fibrous proliferation. This is an analogous change to that occurring in the blood-vessels in syphilitic inflammations. It is not very common, but a moderate number of sections of the hypertrophied mucous membrane will always furnish a few examples. I have never observed it in the œdematous areas themselves.

Blood-vessels are scanty and small. Their walls in some cases are much thickened in their fibrous layer. They are frequently seen in section just beneath the epithelium, as shown in Fig. 3, corresponding to the delicate red tracery seen in the freshly removed polyp. In the stroma they are frequently surrounded by the zone of round-cell infiltration and new connective tissue spoken of above and shown in Fig. 2.

Cyst formation is occasionally a striking feature. Fig. 4 represents the photograph of a section of a sessile œdematous growth*—the so-called polypoid degeneration—under a low power.

You will see that the parenchyma is riddled with these glandular cysts. Microscopically a large number of glands may be seen in various stages of degeneration. Almost always before these cysts reach microscopic proportions the glandular epithelium is completely destroyed. This change is probably due to the plugging of the glandular conduits, and to the loss of elastic support normally furnished by the stroma, but lost in the process of inflammation and serous infiltration. Occasionally a cyst is formed by a dilated blood-vessel. Such a one you see in Fig. 5—another low-power photograph. In this case smaller dilata-

FIG. 3.

ing out, carries down with it only a small part of the normal subepithelial structure. Consequently the glands relative to the extent of the swollen œdematous tissue are scanty, sometimes not seen at all in very many sections. Where the connective-tissue fibers are abundant and the spaces between their bundles small—*i. e.*, where the serous infiltration is slight—glands are seen to be relatively more abundant. The same is true of the blood-vessels and for the same reasons. Operations with the snare or other instruments are frequently more or less incomplete, the pedicle being rarely severed at the base. The apparent pedicle is really nothing in many cases but the tissues squeezed together by the tightening snare. The place of origin of the growths makes a great difference. Around the hiatus semilunaris the glands are not normally so abundant as along the free border of the middle turbinated or on the septum, consequently the polypi that spring from this region do not contain so many of them. When these glands are found they are always extensively affected by morbid changes. The glandular epithelium is swollen and granular; the outlines of the cells are frequently lost and sometimes all the cells in the section of the gland are separated from the walls; occasionally nothing is seen of the epithelium at all, only the round fibrous ring being left. Occasionally in chronic rhinitis and in hypertrophy of the nasal mucous membrane, where œdematous areas have begun to appear, one may observe an encroachment upon a

FIG. 4.

tions of neighboring blood-vessels occur. It is a cavernous angiomatous hypertrophy of the posterior end of the inferior turbinated body. Examinations of other sections of this growth show small areas of œdematous infiltration; but, of course, this vascular dilatation is never observed, or only to a very slight degree, in typical gelatinous polypi. Another method of cyst formation has been described—*i. e.*, the breaking down of the dilated areolar spaces into one or more large cavities. This is possible, but I have never seen it. There are many places, indeed, where the stroma has given way and these spaces communicate with one another in the sections, but I have always thought that

* Specimen kindly sent me by Dr. Knight.

this was principally the result of the hardening and cutting process. The effusion of blood into the tissues and the breaking down of the clot into a cyst I have never seen

FIG. 5.

The effusions of blood which one occasionally sees in the tissues seem to be the result of violence in removal, though it has been described as occurring spontaneously. There is no reason why one of these glandular cysts should not go on growing in a polyp until it occupies the whole of it. This is doubtless the origin of the pure nasal cysts that have been described.

Hyaline bodies resembling those of rhinoscleroma, described as very common by Stepanow,* I have never observed, though I have not adopted any special method of staining to demonstrate them.

Fat cells, or cells containing oil globules, as seen in myxomata, I have never observed.

Nerve fibers I have not looked for. They are said not to exist.

Bone spicula I have never seen in these growths, as described by Zarniko.† In bone disease of the ethmoid accompanying polypi, pieces of bone are frequently included in the mass removed.

On the relation of ethmoid bone disease to nasal polypi Woakes has laid great emphasis. From the fact that ethmoid bone disease frequently exists without polypi and polypi usually exist without bone disease, we are warranted in concluding that neither is essential to the other, but both are the results of some antecedent pathological condition.

I do not mean to deny that *myxoma* may occur in the nose, but I do not believe that is the *usual* character of the growth we know clinically as a gelatinous nasal polypus. Were it so, the frequency of myxoma formation there would far exceed its presence in all other situations.

From the study of the pathological histology of œdematous polypi which I have detailed to you, from much similar work which is merely collateral to the subject matter of this paper, and, lastly, from clinical observation, it seems to me very evident that we have here to do not with a myxomatous tissue, but with one of the results of chronic inflammation of the mucous membrane, which in its early stages is usually hypertrophic. Hypertrophic rhinitis may result (1) in atrophy, with or without œzema; (2) in œdematous nasal polypi, broad-based or pedunculated; (3) in bone disease, especially of the anterior end of the middle turbinate. This bone disease is usually at first hypertrophic or hyperplastic. This may result in rarefaction,

forming bony cysts, or in caries, wrongly called necrosis by Woakes. This caries is frequently the cause of extensive suppuration of the ethmoid cells. All these three pathological states may exist separately or in combination, having had a common origin.

œdematous polypi are frequently associated with empyema of the antrum. The antrum suppuration may be secondary to ethmoid suppuration, or due to the occlusion of the hiatus semilunaris by the polypi. In the vast majority of cases, however, suppuration of the antrum is of dental origin. I mean those cases with recognizable symptoms. The so-called "latent empyema," it seems to me, is found more often in recent literature than in practice.

œdematous nasal polypi are spoken of as recurring after operation. I doubt if they ever recur growing from the stump left after removal. It is almost always from adjacent membrane; scar tissue does not readily become œdematous.

If you will carefully observe in cases of recurrence where you can see the base of implantation, I think you will notice that the new growth does not occupy exactly the same position as the old. Cauterization of the base of these growths, therefore, is not of so much importance as the cauterization of the adjacent mucous membrane. I want, however, to protest here against the statements of the ease with which the base of these growths is reached.

You are all familiar with Zuckerkandl's declaration in his first volume of the inaccessibility of the region from which these growths most frequently spring. In a bloody nose, usually narrow, it is a physical and technical impossibility to see or reach the base of implantation in the majority of cases. Removal of the anterior end of the middle turbinate is only a possible feat in a very few cases. Those growths springing from the free border of the middle turbinate (and they are usually sessile) have, of course, accessible bases. Cauterization here is frequently followed by atrophy of the mucous membrane over a larger area than that actually burned.

Nothing, of course, need be said before this association of the practice (if it really exists) of using a cautery beyond the reach of one's vision in the upper region of the nose.

TWO CASES OF NASAL TUBERCULOSIS.*

By JOHN W. FARLOW, M. D.,

BOSTON.

CASE I.—Mrs. A., twenty-three years of age, consulted me a year ago with the history of considerable discharge in the post-nasal space, and a frequent blocking of the left nostril by large crusts, tendency to bleed from the same nostril, hard, dry cough, and headache in the region of the posterior fontanelle. Putting the finger into the left nostril and touching a sore spot caused pain to be felt in the top of the head, where the headache was generally located.

There was a shallow, elongated ulceration of the lower and anterior part of the left septum. The mucous membrane seemed thick and infiltrated, and the ulcer was covered with a

* Stepanow. *Monatssch. f. Ohrenheilk.*, 1891, No. 5, R. 134.

† Zarniko. *Virchow's Archiv*, No. 128, p. 132, 1892.

* Read before the American Laryngological Association at its fifteenth annual congress.

thin, yellowish-gray secretion. It was fully an inch in length, and about a quarter of an inch wide in the center. The upper part of the nostril was blocked by an easily-bleeding, irregular, reddish mass, about the size of a cherry stone, which seemed to spring from the under side of the middle or upper side of the inferior turbinated bone. On account of the profuse bleeding, I was unable to determine this point, but in a few days I saw that the attachment was to the upper part of the inferior turbinate.

There was nothing abnormal in the right nostril or post-nasal space. There was considerable hypertrophy at the base of the tongue, and swelling and redness of the arytenoids, such as suggests tuberculosis. Examination of the chest was negative. There was not much of any expectoration, and examination of the crusts from the nose failed to show any bacilli. There was no specific history, and specific treatment did not influence the case.

Astringent applications reduced the vascular mass, and there remained a marked ulceration of the inner edge of the lower turbinate. This was shallow, irregular, with a reddened edge, and the secretion which formed on it tended to harden into a good-sized crust.

Curette, lactic acid, and cautery were used on both ulcers, and after a while that on the septum entirely healed, and has not formed again in the last four or five months. That on the inferior turbinate has been more obstinate, and, although nearly healed, manifests a tendency to reappear in a new place. The headache has continued with occasional intermissions. Careful examination of eyes, ears, etc., and all sorts of local and general treatment, have failed to give a clew to the cause or bring about any relief.

CASE II.—Mrs. B., aged seventy-one years, in unusually robust health, consulted the late Dr. Hooper for a soft, obstructive growth of the right nostril. There was no pain or discharge. About a teaspoonful of soft tissue was removed by the snare and otherwise, and considerable hemorrhage resulted. Microscopical examination of the growth showed it to be tubercular. There had existed a curious eruption of the left side of the face, the nature of which Dr. J. C. White was unable to make out.

I saw her a few months ago, and found a soft, reddish mass projecting from the anterior part of the right septum and occluding the nostril. There was a less degree of bulging and thickening of the septum toward the left nostril. The rest of the nose, post-nasal space, and larynx were unusually healthy. There was no cough, and the only symptom was the occlusion of the right nostril.

With the cautery and a snare I have removed the growths from both sides of the septum, and curetted and cauterized whatever irregularities remained. The septum is perforated, and there are still some few places which will need further treatment.

SEARS LABORATORY, HARVARD MEDICAL SCHOOL,
BOSTON, MASS., May 22, 1893.

DEAR DOCTOR: The specimen from the case of Mrs. _____ was a small, flat, nodular growth, quite soft, and of a grayish-white color.

Microscopic examination showed it to be made up of numerous small, rounded centers composed of round and epithelioid cells, scattered among which were numerous giant cells. The centers of these masses had undergone a cheesy degeneration.

The structure was in every way similar to that of miliary tubercle.

A number of sections were stained for tubercle bacilli; but there were none found in those examined.

Yours very truly,

W. T. WHITNEY.

J. W. FARLOW, M. D.

The growth was examined microscopically and pronounced by Dr. Whitney and Dr. Councilman to be undoubted tuberculosis. Dr. Whitney remarked that it was unusual for so large a tuberculous mass to project on to a mucous surface and not ulcerate. No ulceration existed when I first saw her.

Dr. White has recently decided that the eruption on the face is probably tuberculous and it has much improved when treated locally with that diagnosis in mind.

The nose is certainly not a favorite place for the growth of the bacillus of tuberculosis and very few cases of its occurrence are reported. Two forms are generally described—the ulcerating and the proliferating, with increased new growth. My second case belongs to the latter class. There was an infiltration with tubercular elements and resulting enlargement of the septum sufficient to occlude a good-sized nostril, but no ulceration or discharge.

The first case is a chronic, obstinate ulceration of the septum and inferior turbinate, with a soft, vascular, hypertrophied mass springing from the inferior turbinate, of low vitality. Although not confirmed by microscopic diagnosis, I think I am justified in calling it tuberculosis. This did not have the form of the common ulcer of the septum, but was long and narrow, extending nearly half the length of the septum. There was no history or sign of specific disease, and specific treatment was of no avail. Ulcerations of the turbinate are very uncommon, and in this case, following upon the soft vascular growth, were unlike anything I had seen before. Calling such cases scrofulous or lupoid is only begging the question, and, to my mind, less reasonable than to place them in the category of tuberculosis.

DISEASES OF

THE ACCESSORY SINUSES OF THE NOSE,

AND AN IMPROVED METHOD OF TREATMENT FOR SUPPURATION OF THE MAXILLARY ANTRUM.

By GEORGE W. CALDWELL, M. D.,
INSTRUCTOR IN THE NEW YORK POLYCLINIC, ETC.

The frequency with which sinus disease is recognized is in proportion to the care with which the sinuses are explored. An examination of the nose is not scientifically correct until by transillumination and other means the condition of the sinuses has been ascertained. Sinus disease is not by any means rare, although seldom mentioned in literature. In three hundred cadavers examined by Gradenigo (*Annales des mal. de l'oreille*, No. 8, 1891), nineteen cases of empyema of the maxillary sinus were found, of which six were bilateral. The proportion of cases in which the affection is recorded as bilateral varies considerably among observers; for instance, Zeim (*Monatssch. f. Ohrenheilk.*, Nos. 2, 3, and 4, 1886) gives the proportion of bilateral to unilateral as one to two. MacDonald (*Dis. of the Nose*, London), in a series of thirty-five cases, found only two cases to be bilateral, while Lichtwitz, of Bordeaux (*Journal of Laryngology, Rhinology, and Otology*, London, April, 1892), found in forty cases twelve to be bilateral. The latter observer found large numbers of pneumococci, streptococci, and other bacteria, and Luc found the *Strepto-*

coccus erysipilatos in the pus from an antrum. It is evident that such a favorable culture medium is a constant menace to the health of the patient, and clinically it is observed that a large number of cases of purulent sinus disease pass into pulmonary tuberculosis.

The subjective symptoms are frequently modified by the concurrent intranasal disease, such as polypi or hypertrophy. Discharge from the nose is not necessarily large, and may be variable, or it may pass into the rhinopharynx, where it dries in the air current or drops into the throat, exciting cough.

Pain is perhaps the most constant symptom, although if drainage is free it may be slight or absent, except when an acute cold or congestion obstructs drainage. When present, if from *antral* causes, it is greatest in the face; if from the frontal sinus, it radiates from its neighborhood, while pain from the ethmoid cells is referred to the orbits. Frequently the pain is periodic in character, and there is tenderness over the nerves. Decomposition of retained secretions may generate an odor which may be subjectively or objectively unpleasant.

In the diagnosis, transillumination should not be depended upon to the exclusion of other valuable means of diagnosis. Beyond dispute the one absolute proof is the detection of pus escaping from the sinus. This may be secured in all the cells without resorting to exploratory operations. It will be remembered that the frontal, maxillary, and anterior ethmoidal sinuses open in close proximity to each other, opposite the anterior tip of the middle turbinate body, behind a semilunar fold of mucous membrane, the concavity of which looks upward and backward. The relative position of these openings is of diagnostic value. The ostium maxillæ is by far the largest opening, and occupies the lowest position of the crescentic space behind the semilunar fold. Into the upper arm of this crescentic space opens the duct from the frontal sinus, while more protected under the middle turbinate is the opening into the anterior ethmoid cells. This semilunar fold acts as an imperfect valve to the maxillary sinus, and incidentally guides fluids from the higher cells into the antrum, as I have repeatedly demonstrated on the cadaver.

For this reason the diagnosis of empyema of the antrum is not sufficient until the frontal and anterior ethmoid cells have been excluded. The antrum may be the *receptacle* (not the origin) of pus, or become involved secondarily. A method of diagnosis, therefore, which shall be exact and inoffensive is of great importance. If pus is formed in the middle meatus and the olfactory slit is clear, it must come from the anterior group. The discharge being removed and the middle meatus cocaineized, the position of the appearance of the first drop is significant. Pus rolling over the lower portion of the hiatus semilunaris always comes from the antrum. If it first appears in the upper arm of the hiatus, it must come from the frontal sinus, while if the anterior ethmoid cells are suppurating, discharges will escape from under the middle turbinate body. Diseased cells, however, may not be full to overflowing at the time of the examination. It is therefore well to insure the diagnosis, by washing the frontal sinus and

antrum with an aseptic solution by means of a small flexible silver catheter. This is not difficult to do after cocaine has been applied, if the operator is familiar with the position of the openings. The condition of the return water will show the state of the cells. The practice of injecting hydrogen peroxide should be mentioned only to be condemned. The cells are in too close proximity to the brain to make the pressure produced by the escaping gas safe or justifiable. The antral exploratory operation advised by Zeim (*Monatssch. f. Ohrenheilk.*, Nos. 2 to 4, 1886) of drilling a small opening through the alveolar arch is entirely unnecessary, as is that proposed by Lichtwitz (*Journal of Laryngology, Rhinology, and Otology*, London, April, 1892) of puncturing the antrum through the inferior meatus with a trocar. A diagnosis may always be established by inspection, irrigation, and transillumination.

If in the acute stage the normal opening is enlarged, to allow free drainage, and the sinus frequently irrigated with antiseptic solutions, resolution will usually occur; but in the chronic condition, with polypoid degeneration of the mucosa, and deposits of caseous material, nothing less than free opening, curetting, and draining will effect a permanent cure.

The frontal sinus may be freely opened by enlarging the infundibulum through the nose with the curette, and the sinus irrigated and medicated by means of a soft silver catheter. I have educated patients to catheterize their own frontal sinus for home treatment. The old operation of making a large opening through the forehead is necessary only in cases of extensive exfoliation of necrotic bone. When the ethmoid cells are affected as well, I prefer to open them freely with a clipper and curette as a preliminary operation. As both of these operations are done under cocaine, the repetition is not objectionable. For opening the antrum, various methods have been employed. Hunter's operation, of drilling through the socket of a tooth, is still practiced by some, but no careful surgeon would sacrifice a tooth for that purpose. This operation does not fill the indications, as a small opening does not allow a thorough removal of *débris* and polypoid tissue, and a sufficiently large one would allow entrance of food; and the constant drainage of pus into the mouth is not a pleasant subject for contemplation. The operations of Mikulicz, Thornwall, and Krause (*Berliner klinische Wochenschrift*, 1889), having for their object the opening of the antrum through the inferior meatus by the knife, trephine, or trocar, respectively, are perfectly satisfactory from an æsthetic point of view; but, unfortunately, in many cases, the inferior turbinate hangs so low that it is difficult to reach behind it high enough to make a sufficiently large opening for free drainage, while a thorough exploration and removal of diseased tissue is impossible. The operation recommended by Christopher Heath (*Transactions of the Odontological Society of England*, November, 1889), of opening through the canine fossa, has the advantage that it is easy to make a sufficiently large opening to allow thorough curetting of polypoid tissue, cheesy *débris*, necrotic bone, or whatever may produce or continue the disease; but it is open to the objection of dis-

charging into the mouth, its tendency to close, and continued pain and tenderness of the face.

My own method in those cases has been to make a large temporary opening in the canine fossa, through which the antrum is thoroughly explored, all deleterious material removed, and the antrum thoroughly cleansed. A large counter opening is then made into the inferior meatus and the primary opening closed. All subsequent irrigation, drainage, and medication is conducted through the opening in the inferior meatus. By this method I have secured the best results, with a minimum of inconvenience to the patient.

The posterior ethmoidal and sphenoidal cells form what may be called the posterior group. Their openings are above the middle turbinated body, and can be studied only in the rhinoscopic mirror. The posterior ethmoid cells drain by several openings above and below the superior turbinated bone; therefore pus found in this region or seen in the anterior examination above the middle turbinated body must have escaped from the posterior ethmoid cells. The usual course of secretion is downward over the posterior extremity of the middle turbinated. The sphenoidal opening is in the posterior wall, at its extreme upper portion, opposite the superior turbinated bone; and the usual course of secretion from it is downward along the posterior wall, close to the septum. The subjective symptoms of empyema of these cells are similar to those of the parallel disease in the other cells, except that the headache is referred to the back of the head, and ocular symptoms are more apt to be of a functional or retrobulbar nature (see Caldwell on Relation of Pneumatic Sinus Disease to Diseases of the Eye, *Medical Record*, April 8, 1893). The treatment is on the same principles as in the anterior group, but is more difficult of access for permanent drainage.

I have enlarged the natural opening of the sphenoidal cell by means of a hook-shaped knife, which cuts only on withdrawal; but the position of the opening is so variable that in some cases I have been unable to find it. Generally a probe, passed through the olfactory slit at the middle of the middle turbinated, will reach the posterior wall near the opening.

The final manipulations must be done with the aid of the rhinoscopic mirror. Treatment of the interior of this cell requires, without doubt, the most difficult and complicated manipulations in nasal surgery.

60 WEST THIRTY-FIFTH STREET.

TRANSILLUMINATION OF THE ACCESSORY SINUSES OF THE NOSE.

By GEORGE W. CALDWELL, M.D.,
INSTRUCTOR IN THE NEW YORK POLYCLINIC, ETC.

The first and essential step in the successful treatment of any disease, special or general, is an accurate, exclusive, and complete diagnosis. Coincident with refinement of diagnosis comes rational treatment, directed to the primary and sustaining cause, and thereby comes the success of modern surgery and medicine. In the so-called special

branches of surgery this has perhaps been more apparent from the concentrated attention which they have received from their devotees. Not many years ago chronic nasal catarrh or post-nasal catarrh were regarded as sufficiently accurate diagnoses to assign to certain conditions. We then learned there were many varieties dependent upon some demonstrable and removable mechanical obstruction or irritation. Yet there remained, after the visible intra-nasal lesions had been corrected, or in which none could be demonstrated, a large class with more or less obscure manifestations in which the respiratory function of the nose was not affected, either directly by large growths producing mechanical obstruction, or indirectly by irritation of the sensitive areas producing hay fever or asthma. When we shall have better diagnostic facilities for exploring the accessory sinuses of the nose, our list of diagnoses will decrease and symptoms increase. That great class of mere symptoms which are dignified by the text-books with such names as chronic rhinitis, suppurative rhinitis, post-nasal catarrh, some varieties of atrophic rhinitis, ozæna with varying degrees of offensive breath, and a large share of facial neuralgias, will disappear from literature as diseases *per se*, and be recognized as symptoms only of sinus disease.

In difficult cases any means which will enable us to investigate easily regions heretofore unexplored or explored with difficulty will be worthy of our study. Such a means may be found in the transillumination of the sinuses by means of the miniature incandescent electric lamp.

For this test there is required a battery capable of developing from five to ten volts, a resistance coil or rheostat for regulating the current to the resistance of the lamp, and a four or five candle-power lamp with switch handle. For an oval lamp I prefer one with a large globe, as the glass does not become hot so quickly. Instead of the complicated lamps with tongue-depressing attachments, I prefer to use ordinary insulated wires, over which rubber tubing is drawn. This allows easier closure of the lips, and is comparatively inexpensive.

The method of examination of the antrum is as follows: The room being perfectly dark, the lamp is placed in the center of the mouth, the lips are closed over the connecting rubber tube, and the connection is made. If the antra are normal, the face will be instantly suffused with a ruddy glow, its brightness differing in different regions according to the thickness of the solid media. The brightest spots will correspond to the thinnest walls—for instance, at the lower margin of the orbit, where the superior portion of the antrum approaches nearest the surface, there appears a crescentic bright spot. The sides of the nose are also bright for similar reasons. The intensity of illumination is not the same for all persons, although constant in the same person. It is brighter in blondes and in the anæmic, and is in inverse ratio to the resistance to transillumination offered by the tissues through which the light must pass. The picture of the illuminated face in health is a striking one, and presents a certain distribution of light which may be termed the normal relation of light and shade. Variation of intensity, if bilateral, is of little importance if there is

the normal relation of light and shade. Variation of intensity in the two sides is very significant, and indicates disease of the darker side.

If the light in its course encounters an abnormal substance, the illumination will be affected—decreased, increased, or distorted. Turbid fluid, pus, cheesy *débris*, or polypoid degeneration of the mucosa, and solid tumors of the antrum, produce darkening of the entire side of the face; while syphilitic, tubercular, or cancerous deposits produce corresponding shadows. On the other hand, a large mucous polypus, by its translucency, higher refraction, and globular form, will concentrate the light and increase the brilliancy. To confirm a diagnosis it is sometimes advantageous to observe the transillumination *intra nares*. The floor of the nose, unless the palate is diseased, transmits clearly. If the outer wall is in umbra, the diagnosis of antral disease is certain. The ethmoid cells are generally considered as outside the field of transillumination; but I have been able to get trustworthy evidence of their condition by applying the small lamp which I devised for transillumination of the mastoid cells against the orbital tissues, between the eyeball and the inner orbital wall, and observing through the nose the illumination of the ethmoid cells and the superior meatus. For the examination of the frontal sinuses the lamp, protected by soft rubber tubing, is placed against the under surface of the supra-orbital ridge, just internal to the supra-orbital foramen or notch. In health the illuminated area corresponds to the extent of the frontal sinus, extending somewhat over the median line, on account of the tenuity of the dividing septum or its eccentric position. If there is suppuration of these cells, this area is in umbra, due to the turbid pus or thickened mucous membrane. The method of transillumination of the mastoid cells for the diagnosis of mastoiditis interna (first published by the writer) will be found in the *New York Medical Journal*, July 15, 1893.

With reasonable accuracy of application, transillumination is one of the most valuable agents of diagnosis which we possess. Very little technicality is required in its use, and, as it gives no inconvenience to the patient, it may be employed when other means are inexpedient.

45 EAST FORTY-FIRST STREET.

A CONTRIBUTION TO THE STUDY OF CLUBHAND.*

By REGINALD H. SAYRE, M. D.,

ORTHOPEDIC SURGEON TO BELLEVUE HOSPITAL, OUTDOOR DEPARTMENT.

CONGENITAL clubhand is a deformity of very much less frequent occurrence than clubfoot and its cause is involved in great obscurity.

There are clubhands of the acquired variety caused by vicious cicatrices as a result of burns, by paralysis of certain muscles or contraction of others from central nervous irritation, or in other cases resulting from injuries to the

bones of the hand or forearm, but these do not properly come under the head of clubhand such as I wish to mention. As examples of these acquired forms I might mention the following cases:

In the *Philadelphia Medical News*, May 12, 1888, J. K. Young reports a case of clubhand, due to irritation of the brain, which disappeared on the removal of the disturbing influence. The infant was delivered by forceps after a protracted labor and the left side of the head much crushed. A large hæmatoma formed here, and subsequently the right hand was markedly adducted and the fingers and thumb flexed, and the hand was flexed at the wrist, forming almost a right angle with the forearm in the radiopalmar position. The muscles on the radial side of the forearm were firm. The hæmatoma was incised and profuse bleeding followed, and subsequently the deformity gradually subsided, disappearing twenty-four hours before death, which occurred some days later. At the autopsy a fracture of the left parietal bone was found over the position occupied by the ascending frontal and parietal convolutions which had been subjected to great pressure from the effused blood.

Bilhaut, in the *Annales d'orthopédie*, May, 1893, relates a case of clubhand which was supposed to be congenital, but which was really the result of a fracture of the ulna at birth, or soon after, with subsequent loss of bone from suppuration, giving rise to inequality in the length of the bones of the forearm, causing sharp deflection of the hand toward the ulnar side. For the relief of this condition he proposes to remove a portion of the radius and so make it of equal length with the ulna.

The congenital cases of which I wish to speak are of a different kind and may be divided into three varieties: 1. Those where the skeleton is complete and well formed. 2. Where the skeleton is complete but ill formed. 3. Where the skeleton is incomplete and distorted. It is said by various writers that the majority of cases come under the third head, but in the author's personal experience this has not been so, only two of the five cases that have fallen under his observation showing absence of portions of the skeleton; but of course this number is far too small to be used in drawing conclusions of any sort.

In four of these patients there was clubfoot of some variety, and in one case a hypertrophy of one great toe, and the large majority of reported cases are associated with abnormalities of development of some part of the body.

The direction of the deformity may be either in flexion or extension, abduction or adduction, or a combination of two, the most frequent seeming to be the radiopalmar variety.

In those cases where the bones of the hand and forearm are present the prospects of a good result are more favorable than where there is absence of one or more bones. In these milder cases, when seen early, it is sometimes possible to restore the hand to proper shape and function by constant manipulation and retention of the parts in an improved position by some fixed dressing, as, for instance, the plaster-of-Paris bandage, changing the dressing from time to time as the deformity is reduced. Section of the

* Read before the Section in Orthopaedic Surgery of the First Pan-American Medical Congress.

tendons, or ligaments, or fascia may become necessary, especially if the case is not seen in the early stages.

Many of these structures are so situated as to make open section much more preferable than the subcutaneous method, and if the flexor tendons have to be divided it would seem better to operate in the forearm instead of the hand, and to split the tendons longitudinally, and, after having gained such additional length as was needed by sliding the ends past each other, to suture them together once more. I have seen two cases where the deformity was due to shortened flexors of the fingers, one of which had been previously operated on in Baltimore by section of the flexor carpi radialis and flexor carpi ulnaris with great improvement as to function, according to the statement of the parents, but the hand was much distorted and the fingers could be extended only when the wrist was flexed sharply on the forearm. In this case the parents were obliged to leave town before any operation was practicable; and in a second, of similar though less aggravated charac-

upper and lower extremities both being markedly smaller than their fellows. This might possibly be accounted for by disuse, as, on account of the very severe form of clubhand and clubfoot, the boy had depended almost altogether on the left half of his body for assistance. The clubfoot was an extreme varo-equinus and was treated by deep subcutaneous incision in the sole of the foot and tenotomy of the tendo Achillis, the foot then being immediately replaced in the normal position by means of Bradford's clubfoot twister, it being necessary to employ a very considerable amount of force to effect reduction. The foot was then kept in position by plaster-of-Paris boots, renewed about every three weeks, until at the present time his foot is practically in a normal shape.

The clubhand was almost the counterpart of one described by Kirnisson and Longuet in the *Revue d'orthopédie*, January, 1893, and which they had an opportunity to dissect. The radius and thumb were absent, as well as the first metacarpal bone and a certain number of the carpal bones. Exactly which of the latter were absent I am unable to state. The ulna was curved in its middle at an angle of about 30° toward the side where the radius should have been. The hand was almost at

FIG. 1. Congenital clubhand before and after operation.

ter, the presence of inflammation of the cervical vertebrae made it inexpedient to give an anæsthetic, and the operation was therefore postponed.

In a double congenital clubhand at present under treatment the position has been very markedly improved by manipulation and plaster-of-Paris bandages.

Another case of the more aggravated kind has also come under my observation, and these are sufficiently rare to warrant me in describing it at length.

R. B., aged nine years, was seen by me in December, 1892, having a congenital clubhand and clubfoot of the right side, and also a lateral curvature of the spine, the concavity being on the right side. The lateral curvature was apparently due to the imperfect development of the whole right half of the body, the right

right angles with the forearm, bent toward the radial side and flexed on the forearm. The carpus did not articulate with the ulna, but was attached to it by means of firm ligamentous bands.

I first did an osteotomy of the ulna to correct the curve, and, after the bone had firmly united in a straight line, endeavored to stretch the contracted tissues on the side of the arm where the radius should have existed by means of adhesive plaster attached above and below the wrist, and passing around the ends of a wooden splint, which was fastened to the forearm.

After several weeks of traction the hand could not be drawn down far enough to permit the ulna to slide above the carpus, although a considerable elongation of the contracted tissues had been effected. It had been my intention to en-

deavor to form an artificial joint between the lower end of the ulna and the carpus, but on cutting down upon the bones I found that after freeing the end of the ulna from all ligamentous attachments it was impossible to draw the carpus clear of it, and I therefore removed what I took to be the os magnum and unciform. The scaphoid and semilunar apparently did not exist, as in the case which Kirrnisson and Longuet describe. The tip of the styloid process of the ulna was then cut off and the end of the bone inserted into the gap in the carpus formed by the removal of the carpal bones. I had originally intended to wire the bones fast in this position, but on second thought determined to leave the ulna free, thinking that a more serviceable hand would result from this method, and that the bones could be wired together later on if necessary. This operation, of course, shortened the upper extremity still more than Nature had already done, but it seemed to me wiser than the very extensive division of tendons and muscles which would have been required in order to permit the carpus to be pulled down to the extremity of the ulna. The hand was dressed in a straight position, and after about three weeks movements of the wrist were made with the object of creating, if possible, a serviceable joint which should be under the control of the patient.

The position of his hand before and after the operation is shown in the accompanying photographs (Fig. 1), and the boy's control of his motions and his ability to grasp objects is greater now than it was before the operation, while his appearance is vastly improved. He is still wearing an apparatus with a joint at the wrist, allowing flexion and extension, while retaining the bones in a better position than they assume when left to themselves.

In the case described by MM. Kirrnisson and Longuet * the shape, general appearance, and situation of the defective bones correspond so closely with the case I have just

FIG. 2 (after Kirrnisson and Longuet).—B, biceps whose tendon passes in front of the elbow to join the muscles of the forearm; CB, coraco-brachialis; Ba, brachialis anticus; Tr, triceps; R, flexor carpi radialis; G P, palmaris longus; Fd, Fp, superficial and deep flexors; M, median nerve; C, ulnar nerve.

narrated that I think it worth while to quote quite largely from their description of the autopsy (Fig. 2).

Muscles.—Arm.—At the upper end there was a complete absence of the long portion of the biceps; the short portion seemed to be normal. At the lower end the tendon which is inserted into the bicipital tuberosity was absent, and the biceps was gradually merged into a rectangular muscular fasciculus in front of the elbow joint. The brachialis anticus was remarka-

bly small. The other muscles of the arm were normal, but were very slightly developed. On the anterior surface of the forearm the muscular anomalies were so marked as to render it difficult to recognize what muscles were present. There was no pronator radii teres. On the inner border there was a muscular fasciculus continuous with the rectangular muscular mass spoken of above, which below spread itself out at the edge of the carpus, and seemed to correspond to the palmaris longus. The flexor carpi ulnaris was absent. The superficial and deep flexors were in a confused group at their upper extremities, and it was impossible to separate the one from the other at their lower insertions in each of the three last fingers, counting from the ulnar side of the hand. There was no flexor tendon going to the atrophied finger which corresponded to the index; there was no flexor proprius pollicis nor pronator quadratus. On the posterior surface of the forearm the supinator longus and brevis were absent. An undetermined little muscle, which was confused with the other muscles of the posterior surface of the forearm, was inserted toward the external part of the carpus, and represented the radial group. A little muscle fiber ran from the epitrochlear fossa to the internal edge of the carpus. There was no anconeus and no extensor minimi digiti. A single muscle fiber went to the ulnar side of the second finger, representing the extensor communis digitorum.

Hand.—On the outer border of the hand there were no muscles to form the thenar eminence; three lumbricals were present; there were no interossei.

Nerves.—The median nerve was normal. The ulnar passed the elbow in the usual position and was lost on the inner side of the hand. The radial sprang from a common trunk with the musculospiral and was lost on the forearm.

Skeleton.—The scapula and clavicle were well formed. The humerus had no bicipital groove. The musculospiral groove was normal. The elbow joint was very much relaxed; only the trochlear surface of the humerus was covered with cartilage.

The sigmoid cavity of the ulna was well shaped, but allowed only slight movement of flexion and extension of the elbow joint. There was a very sharp anterior curve in the ulna, which made the styloid process very prominent. The radius was absent. The carpus consisted of five bones—two of the first row, the cuneiform and pisiform, and three of the second row, the trapezoid, os magnum, and unciform. The scaphoid, semilunar, and trapezium were absent. The two internal metacarpals were also absent; the other respective phalanges were normal, but the index and the second metacarpal, which it supported, were very short. There was no thumb.

The most extensive article on the subject is that of Bouvier in the *Dictionnaire encyclopédique*, in which are arranged in tables all the cases reported up to 1871. Of the dissections of several cases he gives minute details, and also illustrations of the anomalies, which correspond very closely to the defects in development found in the present case. In regard to treatment but little is said, except that stretching and tenotomy are useful in certain cases, and may be supplemented by apparatus.

Le Dentu, in Jaccoud's *Dictionnaire*, also enters largely into the description of this affection, but says little as to treatment.

* *Revue d'orthopédie*, January 1, 1893. Nouveau cas de main bote congénitale.

Bradford and Lovett, after mentioning the different positions in which the hand may be found, say in regard to treatment that in the worst cases, where there is much bony deficiency, the choice lies between amputation and doing nothing. In the milder cases of resistant muscles stretching by manipulation and apparatus may be efficacious. In general, the treatment must be varied according to the severity of the case.

St. Germain divides clubhand into three groups, similar to those I have mentioned above. Three such cases are in the Dupuytren Museum, and are mentioned by Malgaigne in his *Leçons sur la chirurgie orthopédique*. He suggests manipulation and the employment of apparatus to remedy the deformity.

Redard recommends manipulation and massage in young children where there is but slight fibrous or tendinous resistance; tenotomy is to be done only on the flexor carpi radialis, ulnaris, and palmaris. He does not think very highly of the various orthopedic appliances, and believes that resection and arthrodesis are very rarely indicated.

Hoffa goes quite extensively into the various varieties of faulty development of the upper extremity which may give rise to clubhand. That due to absence of the ulna is very rare, Burckhart and Birnbacher having been able to find only seven reported cases. In regard to treatment, Hoffa mentions massage and retention by means of apparatus, but gives almost no details, while Holmes and Owen are equally brief in their remarks on this point.

The operation which I practiced in the case just mentioned is, as far as I have been able to review the literature of the subject, the first of its kind yet described.

The ulna does not stay in its place as well as I should wish, and if I were to operate in a second similar case I should endeavor to remove the carpal bones without severing the posterior ligaments, and so leave a pocket into which the end of the ulna might be placed, and I may still perform some such operation on this boy if his hand does not seem sufficiently useful.

In a case described by Bouvier, the specimen from which is in the Dupuytren Museum, such of the carpus as is present articulates with the ulna on the side where the radius should have been, the radius being absent. In such a case the proper operation would seem to be the division of the ulna just above the articulation with the carpus, and to turn it at right angles, letting the outer surface reunite with the cut end of the ulna, and thus bring the hand into a straight line with the arm, at the same time preserving the wrist joint.

The anatomical peculiarities of these cases are such that each must be judged by itself, and this brief sketch of the subject is simply offered as contributing to the scant literature of a subject on which much may still be said.

ALUMNOL IN DISEASES OF THE SKIN.

A PRELIMINARY REPORT.

By WILLIAM S. GOTTHEIL, M.D.,

DERMATOLOGIST TO THE NORTHWESTERN DISPENSARY
AND THE GERMAN WEST-SIDE DISPENSARY, NEW YORK;
PHYSICIAN TO THE LEBANON HOSPITAL.

ENCOURAGED by their success in the discovery of dermatol and the continued reports of its value, Messrs. Heinz and Liebrecht have recently presented us with a new compound which they have called *alumnol*. In its chemical composition it is a sulphonaphtholate of aluminium.

The discoverers set out with the idea of endeavoring to find an astringent which should be at the same time an antiseptic, and which should also be free from certain marked disadvantages which are present in almost all our available remedies of the class in question. These are almost all organic or inorganic salts of the heavy metals, and they form insoluble albuminates with the fluids of the tissues. This indissoluble coating confines the astringent and antiseptic action of these compounds within very narrow limits, and is the reason why their action is so very superficial.

Aluminium seemed to be the most promising of the lighter metals, and a long series of experiments were made in the attempt to find a compound of it that possessed the desired qualities. The organic salts of the metal, both of the fatty and the aromatic series, were systematically investigated, without any of them being found suitable. Then the double salts of tartaric acid with aluminium and the phenol compounds were tried, but with the same result. At last the sulphonic-acid compounds were reached, and the desired combination was apparently obtained.

Heinz and Liebrecht have given us in *alumnol* a naphtholsulphonic-acid salt of aluminium. It contains five per cent. of aluminium and fifteen per cent. of sulphur. It is a light, fine, white powder, non-hygroscopic and stable. It is soluble in water to the extent of forty-five per cent., and forms a permanent solution. It is freely soluble in glycerin. In alcohol it is only slightly soluble, and forms a blue fluorescent solution. It is soluble in ether. It strikes a blue color with ferric chloride even in very small quantities. It gets darker on exposure to air, whether in solution, suspension, or in mixture. This, however, only renders it less

sightly; it in no way interferes with its chemical or therapeutic properties.

Alumnol solutions are moderately acid, and they precipitate albumin and gelatin. But here at once we notice a marked and important difference between it and the other astringents that behave in the same way. The alumnol precipitate is soluble and redissolves in an excess of the albumin and gelatin, and the drug would thus theoretically possess penetrating and solvent powers far beyond those of the ordinary remedies of its class. In a fluid medium, such as pus, and especially where pus is compelled to flow out through narrow channels, it would seem to be especially valuable.

Heinz and Liebrecht have made an extended series of experiments to determine the properties of the new drug,* both in the laboratory and in practice. Its antiseptic action was not found to be very marked. Cultures of *Bacillus anthracis*, *Micrococcus prodigiosus*, etc., survived in it for over twenty-four hours. It did, however, prevent their further growth; 0.01-per-cent. solutions hindered the development of the organisms of cholera, typhus, anthrax, pneumonia, and others, while 0.04-per-cent. solutions stopped all further growth. The astringent action, on the other hand, was very marked. As dilute a solution as one of 0.0025 per cent. produced vascular contraction in the mesentery of the frog, and the reaction became very marked when strengths of 0.01 per cent. and over were reached. The exudation of leucocytes in the vessels of the inflamed mesentery was very markedly diminished or completely stopped by the application of a solution of less than 0.01 per cent. Irritation was observed when the strengths of the solutions reached five per cent., but even with ten-per-cent. solutions no corrosive action was observed.

The diffusibility of the drug was shown by the following experiment: A quantity of a five-per-cent. nitrate-of-silver solution was injected into the right femoral muscles of a healthy rabbit, and the same quantity of an equally strong alumnol solution was injected into the left muscles. When the muscles were removed later, the site of the silver injection was found surrounded by a dense mass of coagulated albumin, and no silver could be found in the direct vicinity. The alumnol had apparently caused no irritation, and in the tissues for half an inch around the site of the puncture the alumnol ferric-chloride reaction could be distinctly obtained.

As regards the action of the drug on the healthy animal and human organism, experiments on rabbits showed that strong solutions (ten to twenty per cent.) caused violent irritation and diarrhoea, but were not corrosive. Death occurred in a few rabbits, but only when the dose injected was very large and frequently repeated. Even hypodermically it required seventy-three grains daily for a number of days in succession to cause death. Sections showed that death was caused by disease of the kidneys evidently due to the aluminium in alumnol. The doses requisite for these ill effects were so large, and the conditions needed so favor-

able, that there is no danger in its use in the human subject in any of the ordinary ways. In point of fact, Heinz and Liebrecht gave the drug internally to several hundred human subjects for long periods, and in larger doses. No unpleasant effect was observed, the urine was unchanged, and more especially contained no aluminium.

Therapeutically, the discoverers used alumnol in gynaecological, surgical, and dermatological cases for a period of more than twelve months. Its action as an astringent and antiseptic was very satisfactory, but it was in its use in diseases of the skin and as an antagonist to the gonococcus that it is of most interest to us. It was found useful in inflammation of the skin, both of the superficial and the chronic infiltrated varieties. Its miscibility with water and the readiness with which ointments, varnishes, paints, and plasters could be made with it, rendered it very desirable in these cases. In the chronic cases a ten to fifty per cent. preparation was employed; in the acute ones a two and a half to five per cent. one was found best.

Chotzen* has used it in over three hundred cases of skin and venereal diseases, and with the best results. He employed it pure, as a ten to twenty per cent. powder with talc and amyllum, as a one to ten per cent. solution in water or alcohol, as a two and a half to ten per cent. lanolin salve, and as a varnish with various proportions of collodion, traumaticin, etc. His results in the most varied skin diseases—in chancroid, urethritis, elytritis, etc.—were so good that it seemed desirable to make further experiments in the same direction. During the months of April and May of this year the remedy was employed in over sixty cases of dermatological, surgical, and venereal nature in the German West Side Dispensary.

Alumnol was used in the following manner:

- | | |
|--|---|
| 1. Alumnol Powder No. 1, 12 per cent. | R Alumnol, 20 grs.;
Amylum, 2.3 drms.;
Talcum, 2.3 drms. |
| 2. Alumnol Powder No. 2, 25 per cent. | R Alumnol, 3.2 drms.;
Amylum, 3.2 drms.;
Talcum, 3.2 drms. |
| 3. Alumnol Collodion No. 1. | R Alumnol, 4 pts.;
Oleum ricini, 5 pts.;
Collodion, 40 pts. |
| 4. Alumnol Collodion No. 2. | R Alumnol, 2 pts.;
Oleum ricini, 6 pts.;
Collodion, 40 pts. |
| 5. Alumnol Ointment No. 1, 1 per cent. | R Alumnol, 3.2 drms.;
Adeps, 8 ozs. |
| 6. Alumnol Ointment No. 2, 5 per cent. | R Alumnol, 3.4 drms.;
Adeps, 8 ozs. |
| 7. Alumnol Ointment No. 3, 12.5 p. c. | R Alumnol, 1 oz.;
Adeps, 8 ozs. |

The remedy thus used gave results that were in some cases extremely satisfactory and even brilliant. In others,

* H. Heinz and A. Liebrecht. Alumnol, a New Astringent and Antiseptic. *Berl. kl. Woch.*, No. 46, 1892.

* Martin Chotzen. Alumnol, neues Mittel gegen Hautkrankheiten und Gonorrhoe. *Berl. kl. Woch.*, No. 48, 1892.

again, its effect was only moderately good, and in a few cases was unable to record any success at all. The following were the results obtained:

I. *Acute Inflammations of the Skin, Vesicular, Impetiginous, and Diffuse Eczemas of the Face, Head, Extremities, and General Surface.*—Eleven cases in all were treated solely with alumnol, generally in the form of the collodion coating.

1. Vesicular eczema of the cheeks; female, aged two years, four weeks' standing. Ung. A. No. 1. Complete cure in less than a week.

2. Eczema of fingers, six weeks old, in female aged fifty-four years. A. collodion No. 2. Cured in nine days.

3. Eczema of the hands and fingers; female, aged twenty-four years; from dyestuffs. Improved under A. collodion No. 2, but withdrew from treatment after a few days.

4. Eczema cruris, two months' standing; female, aged twenty-three years. A. collodion No. 2. Has been [two weeks under treatment and is much better. Is still under observation.

5. Eczema of cheeks in child aged four years. A. collodion No. 2. Patches did splendidly under coating, no new vesicles formed, and the exudation of serum stopped. Impossible, however, to prevent the child from tearing the coating off. Discharged almost well after a month's treatment.

6. Recurrent vesicular eczema of the face and arms. This was a most obstinate case, occurring in a girl aged nineteen years. The most varied treatment, persisted in for months, produced only slight amelioration, to be immediately followed by a fresh outbreak. The first permanent improvement occurred when the entire face and arms were covered with a thick coat of alumnol collodion No. 1. The change was striking and, although a considerable amount of serum would accumulate at times under the coating, forming large blebs, the skin underneath was always improved, less red and angry. She was under this treatment during May and April and is now practically cured.

7. Recurrent eczema of the hands. Another obstinate case. Discharged cured after two weeks' continuous application of Ung. alumnol No. 1.

8. Eczema of upper lip in child eight months old. Ung. alumnol No. 1. Cured in five days.

9. Impetiginous eczema of the ears; boy, aged nine years. Ung. alumnol No. 1. Was much improved after a week's treatment; was then lost sight of.

10. Eczema of cheeks; child, aged three years. Returned once only; improved.

11. Eczema of cheeks; girl, aged six years. Ung. A. No. 1. Rapidly cured.

12. Eczema of face; boy, aged two years. A. Collodion No. 1. Was seen once—ten days after an application—improved.

13. Papular eczema of the trunk; child, aged five months. Ung. A. No. 1. Improved under treatment.

14. Acute general papulo-vesicular eczema of head and body; female, aged eleven months. Ung. A. No. 1. Application seemed to irritate at first, but was soon well borne; at the end of two weeks much improved, redness nearly gone, scaling. Patient was then withdrawn from observation.

15. Acute papulo-vesicular eczema of the face; female, aged forty-five years. Potatrix. Ung. A. No. 1. Did not do well in this case; the patient neglected herself, and probably did not attend to treatment.

16. Eczema nuchæ; no trace of pediculi; boy, aged eight years. Ung. A. No. 1. Prompt improvement. Cured in two weeks.

The general results in these sixteen cases of acute catarrhal inflammation of the skin were therefore very satisfactory. They were partly due, of course, to the protection afforded to the inflamed surface by the ointment and collodion covering, and partly also to the fact that most of the cases were in young individuals and of short standing. Any occlusive dressing does good in these cases. But some of the cases, especially Nos. 6 and 7, were very obstinate ones, in which a great many other methods of treatment had been tried without avail. There were hardly any symptoms of irritation observed due to the preparations of the strength used; in fact, the very slight astringency seemed to have a soothing effect. I should consider alumnol as superior to zinc and bismuth in these cases, as being more uniform in results and more generally applicable.

II. *Chronic Inflammations of the Skin, Squamous and Indurated and Seborrhæal Eczemas.*—17. Eczema of the fingers, eight years' standing; female, aged fifty years. Great thickening and itching. A. collodion No. 2. Improved rapidly under the continuous dressing. In two weeks is noted as nearly well. She then withdrew from observation.

18. General eczema of trunk and face; girl, aged eight years. Has had it in varying degrees since birth continuously. Ung. A. No. 2. The result was a brilliant one. After a short period of treatment the child's body was better, the mother says, than it had been for years. Patient is still under treatment.

19. Chronic eczema of both cheeks; boy, aged four years. Eruption present several months. A. collodion No. 2. The redness and thickening grew less and the patches improved markedly, but it was found impossible to prevent the boy from tearing off the collodion coating. Twice in the three weeks that he was under treatment the patches had almost entirely disappeared. Discharged improved.

20. Eczema of entire face; child, aged eighteen months. Very obstinate case of several months' duration. Was improving a little under Ung. A. No. 2, when an attack of bronchopneumonia caused him to be transferred to the children's class and away from my observation.

21. Chronic eczema of toes and dorsum of feet; female, aged fifty years; has lasted all winter. A. collodion No. 2. Patient remarks the prompt disappearance of the itching. Application every other day so far improved the patient that in two weeks, when she withdrew from observation, she was nearly well.

22. Eczema seborrhœicum of the nose; female, aged thirty-three years. Marked improvement under Ung. A. No. 2, but the redness and scaling reappeared when the treatment was discontinued.

23. Eczema and phtheiriasis of the head; girl, aged twelve years; hair matted together by dense crusts, under which pus had accumulated and ulceration occurred. Considerable loss of tissue under some of the crusts; one ulceration on the vertex measures at least one by two inches. The ulcerated areas were dressed with Pulv. A. No. 2, and Ung. A. No. 1 was applied to the rest of the head after the crusts had been as far as possible removed. Treatment was of long duration, for the case was a very bad one and the child was very refractory as regarded the removal of the impetiginous crusts. In six weeks, however, the scalp was clean, the parasites, nits, and consequent inflammation had disappeared, and the ulcerated spots had entirely healed.

24. Chronic eczema of the backs and forearms of the hands;

male, aged twenty-nine years; much thickening and scaling. Ung. A. No. 3 was used continuously on the parts with satisfactory results. The patient was discharged cured at the end of a month.

25. Eczema of the legs; male, aged forty years. The eruption has been present off and on for some years. Ung. A. No. 3. The patient was under observation for a week only, during which time there was considerable improvement in his disease.

Nine cases of chronic eczema were therefore treated with results that, when the patient submitted to the treatment prescribed, were uniformly good. No absolute failures, and no irritation was remarked, even when a fifteen-per-cent. ointment was used. I should not hesitate in obstinate cases to use a twenty-five or thirty-per-cent. ointment.

III. Syphilitic Inflammations of the Skin, Superficial and Deep-seated; Gummata of the Skin and Subcutaneous Tissue.—

26. Large tertiary ulcerative syphiloderma of the skin of both knees; female, aged twenty-eight years. Pulv. A. No. 3 at her visits on alternate days, and Ung. A. No. 3 to use between times. Patient complained somewhat of burning from the powder, and for the first ten days of treatment there was no improvement, but rather a slight extension of the ulcerative process. Then for a time there was some improvement, but after a month it was doubtful if any progress had been made, and the patient was put on internal and specific treatment. Under that she is now far progressed toward cure.

27. Tertiary tubercular syphiloderma of the sole of the foot; female, aged twenty-one years; a year's standing and intractable. The constant application of Ung. A. No. 3 caused no appreciable change in her condition, and she was finally put on the ordinary treatment.

28. Ulcerative syphiloderma of the right knee, two by three inches in size, and four months' standing; female, aged twenty-six years. Dressed daily with Pulv. A. No. 1. Some progress toward healing was made during the three weeks that the treatment was continued, but it was not satisfactory and was changed to the mixed treatment and mitigated mercurial ointment.

29. Tertiary ulcerative syphiloderma of right popliteal space; male, aged sixty-five years. Daily dressings of Pulv. A. No. 2. After two weeks' treatment with slight improvement he was changed to "mixed treatment" with calomel locally.

30. Cutaneous and subcutaneous gummata of upper third of left leg. The cutaneous gumma only was present, with a large central semi-detached slough, when the patient first applied for treatment at the dispensary. Powder A. No. 1 was applied daily, with considerable improvement; the central slough was gradually detached, and the ulcerated area diminished in size, but in ten days another more deeply seated and very painful mass appeared just to one side of the original ulcer, and it was soon evident that another gumma was forming in the deeper tissues. The patient was sent to the Lebanon Hospital, where the softened deep gumma opened into the superficial ulceration. Iodoform gauze packings with bichloride of mercury, one-per-cent. injections, and the iodide of potassium internally, were then resorted to, with the result of a slow but steady cure.

31. Tertiary papular ulceration of both legs; female, colored, aged twenty years. Ointment A. No. 3 was given to the patient; the results were fairly satisfactory, but she soon began to neglect the dressings, and powder A. No. 1 was applied daily at the dispensary. My last notes after three weeks' treatment show only improvement.

32. Tertiary gummatous ulcerations of the skin and subcutaneous tissue, syphilitic orchitis; male, aged thirty-three years; body all scarred with mementoes of the disease. He had been under my treatment a number of times during the last three years, with fair results, when he was sufficiently inconvenienced to attend to himself. Ointment A. No. 2. The testicular inflammation naturally progressed, though the cutaneous sores improved; but the patient himself remarked that the improvement was much less rapid than in former times. After one month he was put on mixed treatment internally also.

33. Ulcerating gumma of skin over sacrum; male, aged thirty-nine years. Ointment A. No. 3. No improvement was noted, and the patient was finally put on the biniodide mixture.

34. Condylomata ani; female, aged thirty-three years. This disappeared entirely after fifteen days' application of ointment A. No. 2.

In nine cases, then, of ulcerative tertiary syphilitic disease of the skin the results were not good. The moderate improvement noted in two or three cases might have been due to other causes, and would probably have been seen if any other application had been used. Case 34 was cured. In these affections, therefore, alumnol is not to be recommended, especially when we compare its results with those obtained from iodoform, calomel, etc.

IV. Deep-seated or Parenchymatous and Traumatic and Infectious Inflammation of the Skin.—

35. Parenchymatous dermatitis and ulcer; female, aged forty. Ulceration was formerly present, but now there is only the inflammation with redness, thickening, and some scaling. Ointment A. No. 1. Notes show improvement for some two weeks, when the patient withdrew from treatment.

36. Dermatitis ambustionis bullosa; male, aged nine months. Burn of moderate size on arm. Ointment A. No. 1. Progressive improvement, but no more rapid than under any other very slightly astringent and protective application.

37. Traumatic dermatitis of foot; female, aged fifty-four years. Coll. A. No. 1. Made very good progress. The scales were detached and the ulcerations healed under daily applications of the paint. Cured in five weeks.

38. Parenchymatous dermatitis ani, ulcer; female, aged fifty-four years. Disease of twenty years' standing. Powder A. No. 2 to sore, and ointment A. No. 2 to surrounding inflammation. There was considerable irritation from the powder, the leg swelled up, the inflammation increased, and the patient's condition became worse. The powder was evidently too strong, and the treatment was changed.

39. Dermatitis ambustionis bullosa; infant of nine months. Burn occurred two weeks ago. Circular patch on arm two inches in diameter; sluggish granulations. Ointment A. No. 1. Healed in five days.

40. Traumatic dermatitis; male, aged thirty-five years. Hurt leg a week ago, and since then the sore has been spreading. Thoroughly cleansed and disinfected. Ointment A. No. 9. Prompt healing.

41. Bullous dermatitis of chest; blistered seven days ago with a mustard plaster that remained on over night. Male, aged fifty-five years. Healed readily under ointment A. No. 1.

42. Parenchymatous dermatitis of leg. Ulcer two by four inches, one year's standing. Ointment A. No. 2 and bandage. Patient improved, but withdrew from treatment.

43. Infectious dermatitis of finger. Male, aged thirty-seven years. Ointment A. No. 1. Steady progress to cure.

In these nine cases of deeper inflammations of the skin the effect of the alumnol was on the whole a very satisfac-

tory one. Some cases did not improve more rapidly than they would probably have done under other treatment, and one (No. 37) became worse, the application being undoubtedly too irritating. The combination of astringent and antiseptic properties renders the remedy of value in cases where sluggish granulations and adherent necrotic tissue interfere with the healing of the ulcerations.

V. *Parasitic and Contagious Diseases of the Skin*.—44. Trichophytosis capitis; male, aged nine years. Coll. A. No. 1. Was under treatment for a long time, with some apparent improvement but no pronounced result.

45. Trichophytosis corporis; male, aged twenty-three years. Treatment and results the same as in No. 42.

46. Trichophytosis corporis; female, aged fifty-four years. Ointment A. No. 2. Cured in one week.

47. Scabies; male, aged twenty-seven years. Ointment A. No. 2. Improved but did not cure him.

48. Impetigo contagiosa; female, aged nine years. Coll. A. No. 2 effected a prompt cure.

49. Impetigo contagiosa; female, aged fourteen years. Treatment and results the same as No. 48.

50. Erysipelas faciei; male, aged forty-five years. Coll. A. No. 2; excellent result. The inflamed area promptly paled under the coating, and the spreading of the disease was prevented. It had already traveled twice over the entire face and head. Cured in one week.

51. Impetigo contagiosa and eczema intertrigo of the nates. Ointment A. No. 2. Female, aged one year. Cured in one week.

In the eight cases of parasitic and contagious diseases of the skin the result was not marked. Scabies and ringworm behaved about as they did to other similar remedies—certain cases did well, and others remained entirely unaffected.

VI. *Glandular and Vascular Diseases*.—52. Rosacea; female, aged twenty-two years. Improved considerably under ointment A. No. 1.

53. Acne vulgaris of several months' standing; male, aged fifty-three years. It began as an iodic acne, but persists now two months after he has ceased to take drugs. After one vigorous curetting he was put on ointment A. No. 1 with excellent results. Discharged cured in two weeks.

54. Large submaxillary abscess; female, aged thirteen months. Opened, washed out with peroxide of hydrogen, and dressed with powder A. No. 1. Prompt healing.

55. Acne vulgaris; female, aged thirty-five years. Chronic case. Curetting and ointment A. No. 2. Cure.

56. Rosacea; female, aged forty years. Great improvement under ointment A. No. 1.

57. Acne; female, aged twenty-two years. Ointment A. No. 2. Improved under treatment, but was lost sight of.

58. Congenital hyperkeratosis of the entire body. Chronic eczema of trunk, face, etc. Acid. arseniosi, one fiftieth of a grain t. i. d., and ointment A. No. 1. Excellent result on the eczema and improvement of the keratosis after three weeks' treatment.

In these seven cases there were no failures; several were cured and the rest were at least improved.

VII. *Gonorrhea*.—59. Male, aged thirty years. Disease of six days' standing. Alummol, four-per-cent. solution, 3 ij, to water, 3vj. It had no effect on the disease in two weeks and was discontinued.

60. Male, aged thirty-six years. Disease six weeks old. Alummol, 3 ss. to water 3vj. Patient improved under treatment. The discharge became quite watery, but he was lost sight of.

The number of cases of gonorrhœa were not sufficient to draw any conclusion from, but I think the drug deserves trial in chronic cases. It will probably be found about as efficacious and reliable as the other remedies used, or as unreliable. The truth probably lies midway between Chotzen's eulogies and Caspar's report of its uselessness.

Although the foregoing report is based upon a comparatively small number of cases, the experience has been sufficient to establish in my mind the conviction that in alummol we possess a remedy of permanent value in a number of diseased conditions. It is an astringent which is at the same time antiseptic and non-irritating. In its pure condition it might prove irritant, and in one of the cases recorded above it was undoubtedly used in too great concentration, but under ordinary medicinal conditions it has never caused the least pain or trouble. Over nitrate of sodium it possesses the advantage of not forming an insoluble albuminate to stop the further action of the remedy, nor does it stain the clothes. In all inflammatory skin diseases, even the most acute, it deserves a trial. In the chronic form it holds its own with any of the older remedies. In the parasitic diseases it does not seem to possess any marked advantage over other drugs. It succeeds in some and fails in others, as they do. In the syphiloderma its action was not satisfactory. The gonococcus apparently survives in its presence. It possesses some marked advantages over the permanganate of zinc and other older astringent antiseptics in its non-irritating nature.

25 WEST FIFTY-THIRD STREET.

A NEW METHOD OF AIDING IN THE ATROPHY OF UTERINE MYOMA WITHOUT REMOVAL.

By F. BYRON ROBINSON, B.S., M.D.,
CHICAGO.

TWELVE months ago a lady about forty-four years old came to me for severe uterine hemorrhage. On examination, I found a large uterine myoma—as large as a man's double fists. No benefit was gained from hot douches, ergot, and as much rest as she could take under her circumstances. I used electricity, but no appreciable benefit resulted. At the end of two months' treatment she was worse off than ever. She went into the Woman's Hospital in my service. The examinations *per vaginam* revealed much solid exudate and tenderness in the pelvis. A laparotomy on her brought to light such dense and extensive adhesions that it was deemed unsafe to attempt to remove the uterus or tubes and ovaries. In this case I determined to adopt a new plan of procedure. I first tied both tubes at their junction with the uterus with a No. 14 silk ligature, using a long curved needle with an eye in the end. This ligature would destroy the functions of the tubes forever and stop blood from that direction coming to the uterus. The uterus was very large and, set in old solid exudates like a turnip in frozen mud and it was feared that even after the tubes were ligated and functionless

(though not removed) the blood supply was great enough to contain the hemorrhage. So I adopted the plan of ligating the uterine artery for a half or more of its way down the body of the uterus. Two silk ligatures were applied to the uterine artery as it ascends along the body of the uterus.

As the uterine artery ascends along the body of the uterus to meet the ovarian at the junction of the tube and uterus, it is tortuous and hugs tightly the uterine body; but one can easily push the needle between it and the body of the uterus and thus ligate it. In some of the fibroid tumors the uterine artery along the body of the uterus enlarges and beats with a tremendous force. Now, this heavy throbbing of the artery is what induces one to attempt to arrest its action, for it does seem that if such a torrent of blood is checked the uterus would not be fed so well.

In my case nearly two thirds of the way down the uterus the artery received ligatures. The abdomen was closed and the lady recovered. To my great astonishment, the uterus had shrunk to about half its original size in three months. Her profuse hemorrhages stopped and she gained flesh rapidly. Six months after, she was well and the uterus had gone down more than half its original size and felt much more normal in size and shape. Then she appeared perfectly well. Since that time I have done the operation once more, but it is too soon to announce any results.

This new method of operating for uterine myoma consists—1. In ligating the ovarian artery with or without tubal and ovarian removal. 2. In ligating the uterine artery which courses along the sides of the body of the uterus for a half or two thirds its length from the fundus to the cervix. The object is to induce uterine atrophy and avoid the danger of removal of uterine myoma. The mortality of abdominal hysterectomy for uterine myoma is still very high in the most skilled hands and appalling in the hands of amateur operators. In this operation the mortality over tubal removal will scarcely be increased by the additional time and manipulation necessary to ligate the uterine artery coursing along the body of the uterus. I used a well-curved aneurysm needle in performing the operation, thus avoiding the sharp-pointed needle, which might lacerate the vein or artery. One can put the finger and thumb on the artery and feel it beat close to the uterus. A glance at the ever-memorable Hyrtl's representation of the uterine circulation will easily show how the operation can be performed. If it be found difficult to secure the corporeal uterine artery in an aneurysm needle, a long, sharp, curved handled needle could be employed, which could be pushed through a part of the uterine substance, if required, to be doubly sure. It is a curious feature that uterine myomata seem to have a very feeble vitality, and by a slight shock or a slight change of blood in some other direction a myoma will frequently shrink. If a uterine myoma can be made to shrink by a simpler operation than abdominal hysterectomy, the woman is saved from considerable danger and the mutilating loss of an organ. Sweeping removals of organs is a backward movement in the art of surgery. This operation will not suit all fibroids, but it seems to me to be a distinct addition to the operation of the removal of the appendages for "bleeding fibroids" given

to us by Battey, Tait, and Hegar. This operation is entirely original with me, as I have not observed any note on the idea in literature.

34 WASHINGTON STREET.

AN ENORMOUS CEREBRAL TUMOR.

By WILLIAM E. CONROY, A. M., M. D.,

SAGINAW, MICH.

THE phenomenal size of the encephalic tumor here described renders the case, I think, worthy of record, although I am unable to report it as accurately as I could wish, having, unfortunately, lost my notes. The main features of the case, however, are these:

F. H., aged twenty years, American by birth and parentage, came to my office accompanied by his mother, who requested me to examine his eyes, saying that his vision had been failing for about two years. I obtained the following history: F. was an unusually bright boy until his fourteenth year, when he was knocked down and kicked in the head by a horse. The blow rendered him for a short time unconscious, but he apparently recovered completely. Soon after, however, it was noticed that he was gradually losing his hearing. The deafness increased slowly, and, about a year after the accident, paralysis of the right arm and leg developed. Next his speech became affected, and finally his eyesight began to fail. The mother also thought that for the last few years the boy's head had been increasing in size.

Status Præsens.—Height, five feet five inches and a half. Body well nourished, muscles well developed, and plenty of adipose. Measurements of arms and legs of right and left sides show no marked difference. Facial expression rather dull. Tongue protrudes to the left. Sensation blunted over entire right side, right arm and leg, most marked in leg. Paralysis of motion nearly complete in right lower extremity; right arm and hand much weaker than left. Electrical reactions not taken. Head square, of hydrocephalic type; circumference at level of frontal eminence thirty-three inches. *Ears.*—Tympanic membranes normal in appearance; no ankylosis of incostapedial joints. Eustachian tubes patulous. Hears only the loudest sounds, there being apparently no difference in hearing capacity between right and left ears. *Eyes.*—External structures normal. Pupils dilated, the left rather larger than the right, and do not react either to light or to efforts at accommodation. A very marked neuroretinitis in both eyes, that of the left advancing to the atrophic stage. No heterophoria. Vision in the right eye is reduced to recognition of No. L Snellen at a few inches from the eye. With the left eye he can only count fingers at about a foot distant.

Articulation very indistinct. There is a depression in the skull at about the location of the left parietal foramen, but no cicatrix. Pressure over this spot causes pain. The mother states that the boy's appetite is enormous, and that he sleeps well. I think she told me that he had suffered from several convulsive seizures, during which he lost consciousness, but that he did not foam at the mouth or bite his tongue. There are no scars on the tongue. I made a diagnosis of cerebral tumor, probably in the occipito parietal region. This was in August, 1889. I did not see the boy again until the following January, when I was asked to consult with the late Dr. B. B. Ross, of Saginaw, as to the propriety of an operation. The only change that had occurred was that both optic nerves were now markedly atrophied and vision was reduced to perception of a hand placed between

the eyes and a bright light. Dr. Ross agreed with the diagnosis of tumor, and after explaining to the mother the certainty of a fatal issue if the case was left to Nature and the danger of operation, with the extremely slight chance of benefit therefrom, she requested us to operate. Accordingly, on the 2d of February, 1889, Dr. Ross trephined, assisted by Dr. Barber, Dr. Sawyer, Dr. Schemm, the writer, and others. The operation was performed under strict antiseptic precautions, a curved incision being made with its center close to the depression in the skull before mentioned. This depression proved to be an opening in the bone, apparently caused by absorption, the surrounding bone being very thin. About two square inches were removed with trephine and bone forceps, when the dura bulged through the opening very dark, almost black in color. Incision of the dura revealed a hard, lobulated mass, looking very like brain tissue. Trying to pass the finger around the mass showed that it was so extensive that removal was out of the question, though nobody present imagined that it was nearly as large as it afterward proved to be. A small piece was therefore cut off for examination and the wound closed, a drainage-tube inserted, and an antiseptic dressing applied. The shock of the operation was severe, but the patient rallied for a time, and for twenty-four hours seemed to be doing well. On the second day, however, the heart's action began to fail, and death ensued painlessly forty-eight hours after the operation.

Autopsy, twelve hours after death, by Dr. Sawyer. Present, Dr. Ross, Dr. Conroy, Dr. Schemm, and others. Only the encephalon was examined. On removal of the calvaria the entire left half of the cavity seemed to be filled with the tumor, the surface of which resembled very strongly a normal hemisphere, being lobulated and fissured in such a manner that a superficial glance detected but little difference between it and the right hemisphere, which was macroscopically absolutely normal. The tumor was invested with a closely adhering tough fibrous membrane, which sprang from the falx cerebri. There were no other attachments. On dividing this attachment and lifting the enormous mass out of the cavity the left hemisphere was seen lying on the base of the skull, flattened and compressed to the size and shape of the palm of a man's hand. Removing this and the right hemisphere, two smaller tumors were found on either side of the foramen magnum, attached to the dura of the medulla oblongata. The main tumor weighed *one pound eleven ounces* avoirdupois. Its long diameter (antero-posterior) was *eight inches*, transverse diameter *three inches and a half*, and from surface to base *four inches*. Of the smaller tumors, one was of about the size of a plum, the other rather smaller. All three tumors were of very firm consistence and seemed homogeneous throughout. Several sections were made and examined microscopically by Dr. George C. Chase. They proved to be composed of pure fibrous tissue, with here and there a spot where the tumor was undergoing fatty degeneration.

I have reported this case at length from memory on account of the immense size of the tumor—the largest intracranial neoplasm, I believe, on record—and because it affords an almost unique example of what the system will sometimes endure without collapse. Here was a young man with practically but half a brain, and that half pressed upon by its pathological neighbor, yet with heart and lungs perfectly normal, assimilation and excretion going on without interruption, and with even the mental faculties not seriously impaired; for the boy was intelligent, expressed himself well, but for the mechanical difficulty of speech, and, until his sight failed, read much and with enjoyment.

How long he would have lived but for the unfortunate operation it is impossible to say, but there was no sign of vital failure up to that time, notwithstanding the pressure upon the origins of all the left cranial nerves, including the pneumogastric. I send herewith a photograph of the tumors reduced about one third.

To the best of my recollection, we found no abnormality in the cerebellum, pons, or medulla. I can not state from memory the details of the examination of the compressed hemisphere. Potassium iodide was given in large doses without result.

LAPAROTOMY FOR THE REMOVAL OF A PYOSALPINX FOLLOWED BY A FÆCAL FISTULA.

By JOHN R. HINKSON, M. D.,
SURGEON TO THE ASTORIA HOSPITAL, LONG ISLAND CITY, N. Y.

Mrs. S., aged twenty-two, was operated on by the writer for the removal of a pyosalpinx affecting the right tube, which was adherent to the bladder, vermiform appendix, small intestines, and omentum, on May 3, 1891. She made a good recovery from this operation, except for the occurrence of a sinus in the inferior apex of the wound.

Six months after this date she complained of a great pain in the left iliac region which was aggravated by the occurrence of menstruation; and, on bimanual examination, a tumor was discovered to the left side of the uterus in which fluctuation could be plainly detected. She was believed to have another pyosalpinx, and was advised to have an operation performed, to which she readily consented.

The operation was performed, as in the former case, at the patient's residence on January 3, 1892. It was feared, on account of the adhesions met with in the first operation, that the removal of this tumor might prove extremely hazardous; but on making an incision in the median line of the abdomen and exploring with the hand in the peritoneal cavity, the tumor—which was the size of an orange—was found to be entirely free from adhesions, and was removed with little difficulty in connection with the ovary, which latter contained several small abscesses. The sinus was then slit up on a grooved director and thoroughly curetted. This being done, the abdomen was closed with interrupted sutures of silver wire and a drainage-tube inserted in the middle of the wound.

The dressing was composed of iodoform and corrosive-sublimate gauze, over which was applied a layer of absorbent cotton.

The patient vomited considerably for five days, but suffered little pain. The temperature and pulse remained approximately normal till the third day following the operation, when the

pulse rose to 120 and the temperature to 100° 2'. For the first three days nutrient enemata were administered.

January 6th.—Pulse, 100; temperature, 99°; dressing changed; drainage-tube removed; no appearance of suppuration; bowels moved by enema.

8th.—Pulse, 102; temperature, 101°; dressing changed; bowels moved by enema. On January 9th meat was allowed.

11th.—Pulse, 80; temperature, 99° 5'; dressing changed and sutures removed.

18th.—Pulse, 100; temperature, 102°; dressing changed; suppuration at lower extremity of the wound; irrigation with hydrogen peroxide.

20th.—Pulse, 88; temperature, 101°; suppuration on the right side of the insertion of the lower stitch holes.

25th.—Pulse, 73; temperature, 98° 6'; dressing changed; wound apparently healed; bowels moved naturally.

On February 1st a sinus was discovered at the site of drainage and at the inferior extremity of the wound corresponding to the opening of the former sinus. The patient was not permitted to leave her bed for a month after the operation. The sinuses occasioned little inconvenience except for a gurgling she complained of in the inferior one. Carbolic acid was first applied, but without effect. The sinuses were then dilated with laminaria tents and curetted, nitrate of silver being afterward applied.

The superior sinus had healed on July 20th, but the inferior one was in the same state, the patient complaining occasionally of a sensation like the passage of wind.

On August 1st the patient, being constipated, gave herself an enema; and when she had injected about half a pint the water was ejected with considerable force through the sinus, being followed by fecal matter.

The writer considered the above-mentioned occurrence as positive evidence of the existence of a fecal fistula; but as the external opening was very small, being about sufficient to admit an ordinary probe, a radical operation was not considered advisable, and the only treatment employed was the application of a pad of antiseptic gauze strapped on tightly with strips of adhesive plaster.

On May 3, 1893, being two years after the first and one year and five months after the second operation, the fistula was found to be closed.

At this writing, September 22, 1893, the patient is in excellent physical condition; she has increased considerably in weight and is entirely free from pain or any uncomfortable feeling.

The Clinical Society of the New York Post-graduate Medical School and Hospital.—The next meeting will take place in the amphitheatre of the school, No. 226 East Twentieth Street, this (Saturday) evening at 8.30. A paper entitled *Modern Methods of Research in Medicine and Surgery* will be read by Dr. Otto G. T. Kiliani. The members of the profession are invited to be present and participate in the discussion.

A New Hospital in San Francisco.—It is announced that Dr. Levi C. Lane, of San Francisco, has caused a large hospital to be built at his own expense, for use in connection with the Cooper Medical College.

Changes of Address.—Dr. Joseph Collins, to No. 43 West Thirty-ninth Street; Dr. Everett M. Culver, to No. 36 West Thirty-fifth Street; Dr. Charles S. Fischer, Jr., to No. 201 West One-hundred-and-eighteenth Street; Dr. Allan McLane Hamilton, to No. 44 East Twenty-ninth Street; Dr. Irving S. Haynes, to No. 181 East Eighth-sixth Street; Dr. Carl Koller, to No. 715 Madison Avenue.

THE
NEW YORK MEDICAL JOURNAL.
A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, NOVEMBER 4, 1893.

THE MEDICAL SERVICE OF THE NAVY.

The *Brooklyn Daily Eagle* says of the man-of-war New York that her accommodations for the sick and wounded are "grotesquely inadequate," and that the hospital is so situated that its inmates must be subjected to most disturbing and irritating noises incident to the working of the ship. The same paper says:

"The bureau of medicine and surgery of the navy can not possibly approve of such a condition of things. If it is aware of them, it must, from the commonest premises of science and of decency, have protested against them. If its protest has been ignored, the shame for that fact must be due to the absence of any representative of the medical department of the navy from the board whose authority in the construction of vessels of war is final.

"There is plenty of room in the New York for large and decent hospital accommodations. Either further back on the same deck, or, better yet, further back on the gun deck above, plenty of room can be found. If the chief of the bureau of construction can not find such room, the *Eagle* can send a reporter along with him who will show him where plenty of such room can be found in the ship, without even sacrificing the comforts or the luxuries of any person on board, including the boudoirs of the petty officers or of the 'secretaries,' 'writers,' or scribes of officers higher in rank on this floating palace of strength and beauty.

"The attention of the medical men of these two cities of all schools of practice is called to this abuse. Medical journals are respectfully and urgently asked to investigate it and to agitate for its reform. A private interest that sent a ship as large as the New York to sea with hospital accommodations so inadequate and so surrounded with factors of noise, which to the sick is torture, would be prosecuted under the law of any country. Our own Government, the fountain of law, is in this instance a violator of the laws of humanity and will be impeached by public opinion and by the love of mankind for mercy and for justice, if this abuse is not rectified.

"There is plenty of time in which to rectify it. The ship will be here for quite a while. If sent abroad with this abuse unremedied, the shame of the fact and the consequent shame of the Government will be carried across the seas and around the world, wherever this magnificent vessel is visited as an example of the art and power of the United States. The time to begin [this reform] is now, and the policy and determination necessary for its accomplishment must be so resolute that sophistry and mendacious denial can not arrest it or red tape in

any form be interposed against it. The *Eagle*, from its knowledge of this wrong, would feel that it was an accomplice before the fact in the deaths and sufferings of the naval defenders of the country if we did not protest against it."

If the faults pointed out by the *Eagle* admit of remedy before the ship goes to sea, certainly the remedy should be applied. We can not afford to lag behind other nations in our appliances for the care of the sick and wounded on shipboard.

THE STATE LICENSE TO PRACTICE.

WE are indebted to the editors of the *Buffalo Medical and Surgical Journal* for advance proof-sheets of an editorial article prepared for the November number of that journal. It is entitled State Examination for License. In part it is a comment on the new Pennsylvania law, but in the main it is a statement of the practical working of the New York State law, and its accuracy is guaranteed by the fact that one of the editors of the *Journal*, Dr. William Warren Potter, of Buffalo, is a member of the board of examiners.

The writer expresses his conviction that the operation of the law during the two years that the State alone has been empowered to grant the license to practice has more than fulfilled the promises made by the advocates of the measure. "Most of the exemptions having ceased," he says, "the last academic year was a busy one for the New York State medical examiners. There were 327 candidates for license, showing that the estimate of an annual influx of 400 physicians, rather than from 600 to 700 as of old, is very near the mark. It is more than probable that the current year will demonstrate this still more clearly. Of this number, 267 succeeded in meeting all requirements and passing the medical examinations, and are now registered as practitioners of medicine by virtue of a State license. Two hundred and forty-four of these are State [society?] board men, seventeen are homœopaths, and six are eclectics."

It is shown that the revenue derived by the examiners from the fees received is inconsiderable; the statement is made that a new edition of the *Syllabus*, now in press, will be "a scientific model for the systematic study of medicine, as well as a guide for those who contemplate taking the State licensing examinations"; and the article continues as follows: "Some of the effects of the establishment of State boards of medical examiners have been improved methods of teaching, prolongation of terms of study, and the establishment of new chairs of instruction. While in New York State the entire subject of medicine is divided into seven main topics, the questions asked under these topics are so subdivided as to comprehend almost every sub-head in medicine. Realizing the importance of having their graduates well equipped for passing these tests, the means above enumerated have been adopted for the benefit of colleges and the profession. In consequence, teachers of hygiene, medical jurisprudence, and other subdivisions of medicine exist now in fact as well as in name in most of our colleges, a thorough drill and review teaching is a feature of the curriculum, and some of the lecture courses extend over a period of eight months. Under the

direction of the Committee on Legislation of the Medical Society of the State of New York, an auxiliary committee has been at work looking out for the enforcement of the law governing medical registration in every county in the State. They have done such excellent work that to-day every registration recorded since the new law went into effect is known to the society, and where correction of illegal registration has not already been made the penalty of the law will be enforced. In addition, county clerks are now conversant with the conditions regulating registration, and it is more than certain that no new name will be added to the records unless the document on which registration is demanded bears the seal of the regents."

The article concludes with very clear instructions as to the proper course for those to take whose registration does not quite fulfill the requirements of the law.

MINOR PARAGRAPHS.

AMPUTATION AT THE HIP JOINT.

In the *Annals of Surgery*, Dr. Murdoch says that, when it can be applied, Wyeth's method is the best for the temporary arrest of hæmorrhage. The method of operating known as that of Furneaux Jordan he considers the best where the nature of the case will permit of it. In this operation the thigh is amputated, as low down as the condition of disease or injury will permit, by a circular incision. An incision is then made from the top of the trochanter major downward along the femur to the circular incision; the soft parts are dissected from the bone, and disarticulation is accomplished after dividing the muscles and ligaments by strongly abducting the femur. When for any cause neither of these methods is applicable the operation should be performed by means of one of the Racket incisions and the vessels secured as they are exposed in the course of the operation. In military or railway surgery cases may occur in which it is necessary to do the operation with great rapidity. In such cases the antero-posterior flap method is the best. For the permanent arrest of the hæmorrhage torsion of the bleeding vessels is recommended as being less liable to be followed by secondary hæmorrhage, more easily applied, and, involving no foreign substance in the wound, less apt to convey infection.

THE EXCITERS OF MASTOID DISEASE IN CONNECTION WITH DISEASE OF THE MIDDLE EAR.

In a recent number of the *Zeitschrift für Ohrenheilkunde* Dr. Scheibe maintains that when an acute disease of the middle ear leads to bone disease there are present, in addition to the known anatomical causes, such as the pneumatic cells that prevent the outflow of the pus, and the patient's general condition, the following pathological ones: too small and too highly situated a perforation, which also closes too early, the proliferating growth around a central opening, and great swelling of the mucous membrane. In sixteen cases a thorough microscopical examination of the discharge showed that in fifty-six per cent. the *Diplococcus pneumonia* was found, in six cases the *Streptococcus pyogenes*, in one the *Staphylococcus*, and in one some undetermined rounded cocci without a capsule. In other investigations he has found the *Diplococcus pneumonia* present in only twenty per cent. of cases of acute middle-ear disease, so he is inclined to think that this diplococcus specially favors the spread of the disease to the adjoining bones. Dr. Scheibe

seems to have deduced his opinion from insufficient grounds. Sixteen cases can hardly be considered a sufficiently large number upon which to base an estimate of percentage.

THE PUBLIC RECOGNITION OF MEDICAL EMINENCE IN FRANCE.

In a memorial notice on Jean-Martin Charcot, published in the *Johns Hopkins Hospital Bulletin* for September, Professor Osler delicately alludes to the high public status of the physician in France as contrasted with other countries. He says: "A finely tempered individualism, prone though it be to excesses, is one of the glories of the French character. The man in France stands for more than in any other land; his worth and work are there more truly recognized, and there his relative position in the history of art, literature, or science is more justly gauged. Alone among the nations of the world, France honors duly the mighty dead of our profession. Not in the Pantheon only, but in statues, in the names of streets, and in the names of hospitals, one is constantly reminded in Paris that such men as Bichat, Laennec, Pinel, Trousseau, Broca, Bernard, and others have honorably served their day and generation. The memory of Charcot is secure in such a land, and with us, too, it will rest safely, cherished beside that of Laennec and Trousseau."

A MEDICAL LEANDER.

ACCORDING to the newspapers, Dr. Judson Daland, of Philadelphia, recently swam the Strait of Messina, known to the ancients as the whirlpool between Scylla and Charybdis. This feat is said not to have been accomplished before within the memory of the oldest inhabitant of Faro, a neighboring fishing village. Dr. Daland is reported to have said: "The entire swim was made without rest or stimulants, and I restricted myself to the breast and side stroke, not using the back at all. I encountered during the swim strong currents, running apparently in all directions, the direction changing every few moments. These currents were at times warm and at others icy cold. There was a high wind and a choppy sea, making it extremely difficult to breathe. I returned to Messina in good condition and that same evening went to the opera."

THE POSSIBILITY OF CHOLERA INFECTION BY SALTED SHEEP GUTS.

THE *Abstract of Sanitary Reports* for October 20th contains a report from Dr. Dunbar, director of the Hamburg Hygienic Institute, of an investigation of salted sheep guts from a nominally infected locality, for the purpose of discovering how long cholera vibrios were able to exist upon them. The results of the inspection showed that those guts that were infected with cholera vibrios showed evolutionary organisms after having been kept for six hours in a refrigerator, while guts kept at a temperature of 22° and 37° C. showed evolutionary forms after three hours, but not after six.

GRAPE JUICE AND WOMAN'S MILK.

THE *Lyon médical* for October 1st states that the ancients established the curative property of grape juice in certain digestive troubles, dropsies, etc. Chemical analysis, by showing a great analogy between grape juice and woman's milk, affords an explanation of the happy effects that have been demonstrated by the nropathic physicians. This may be judged by the analyses. The grape may contain microbes either when found as raisins suspended under the joists of a country house or in the

fresh fruit. Dr. Schnirer has found the tubercle bacillus in the water in which grapes taken from a basket in the streets had been washed.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 31, 1893:

DISEASES.	Week ending Oct. 24.		Week ending Oct. 31.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	0	0
Typhoid fever.....	43	16	31	14
Scarlet fever.....	60	7	65	3
Cerebro-spinal meningitis.....	7	5	3	3
Measles.....	93	3	104	5
Diphtheria.....	186	40	167	46
Small-pox.....	16	3	9	1

The City (Charity) Hospital.—We learn that Dr. Robert W. Taylor, who has served on the medical board for many years with conspicuous fidelity and ability, has resigned.

The New York Academy of Medicine.—The smoking room and grill room were open on Thursday of this week to the fellows and their invited guests from noon until eleven at night.

Society Meetings for the Coming Week:

MONDAY, November 6th: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society (private) New York; Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Corning, N. Y., Academy of Medicine; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; South Pittsburgh, Pa., Medical Society; Chicago Medical Society.

TUESDAY, November 7th: New York Obstetrical Society (private); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Hudson, N. J., County Medical Society (Jersey City); Androscoggin, Me., County Medical Association (Lewiston); Hampden, Mass., District Medical Society (Springfield); Baltimore Academy of Medicine.

WEDNESDAY, November 8th: New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Metropolitan Medical Society (private), New York; Medical Society of the County of Albany, N. Y.; Worcester, Mass., District Medical Society (Worcester); Pittsfield, Mass., Medical Association (private); Philadelphia County Medical Society.

THURSDAY, November 9th: New York Academy of Medicine (Section in Pediatrics); New York Physicians' Mutual Aid Association (annual); Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y.; South Boston, Mass., Medical Club (private—annual); Pathological Society of Philadelphia.

FRIDAY, November 10th: Yorkville Medical Association (private), New York; German Medical Society of Brooklyn; Brooklyn Dermatological and Genito-urinary Society (private); Medical Society of the Town of Saugerties, N. Y.

SATURDAY, November 11th: Obstetrical Society of Boston (private).

Obituaries.

ALFRED LUDLOW CARROLL, M.D.

DR. CARROLL died at his home, in New York, on Monday, October 30th, after a long illness from pulmonary tuberculosis, in the sixty-first year of his age. He was a graduate of the Medical Department of the University of the City of New York, of the class of 1855. A large part of his professional life was spent on Staten Island, but for several years past he had done a consultation practice in New York. For a number of years, up to the time it ceased to be published, he was the editor of the old *Medical Gazette* (not the subsequent publication that was evolved out of the *Hospital Gazette*), which he conducted most ably and acceptably. He was a very forcible writer and an editor of great discernment. In his later years he was an earnest student of public hygiene. He was a member of the New York County Medical Association and of the New York State Medical Association, and for several years edited the State association's *Transactions*. Dr. Carroll was an accomplished physician and a most upright and amiable man.

Proceedings of Societies.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Fifteenth Annual Congress, held in New York on Monday, Tuesday, and Wednesday, May 22, 23, and 24, 1893.

The President, Dr. MORRIS J. ASCH, of New York, in the Chair.

(Continued from page 510.)

Some Remarks on the Structure of Edematous Nasal Polypi.—Dr. JONATHAN WRIGHT, of Brooklyn, N. Y., read a paper on this subject. (See page 521.)

Dr. MULHALL: I wish to take exception to one statement made by Dr. Wright—namely, that atrophy is the result, commonly, of a preceding hypertrophy. I wish to take exception also to the generally received opinion that atrophic rhinitis is subsequent to hypertrophic rhinitis. I believe I was the first to point out, some eight or nine years ago, that atrophic rhinitis, in ninety per cent. of cases, was a disease of childhood, and was often the result of an acute inflammatory process, scarlet fever, measles, etc., resulting in acute atrophy. In Burnett's work on Diseases of the Nose and Ear he has the word *cirrhotic* in parentheses after the word *atrophic*, as though the two terms were convertible. Long-continued hypertrophy may result in cirrhosis, but not in atrophy. This rule holds good in the nose, as it does in other organs in the body. Cirrhosis of the liver is the result of a long-continued hypertrophy. Atrophic rhinitis is a disease almost *ab initio*, and is not the result of hypertrophic rhinitis.

Dr. PORCHER: I have two instruments which I wish to present to the association. The first is a recent modification of a self-retaining palate retractor, the description of which appeared in the *Medical Record* in April, 1888, and previous to that of any similar device. In its present form, being made of aluminum and the slide being without screws and catches, the action is entirely automatic and not at all clumsy. The hook is a solid band and is bent backward and divided at the end so that it does not bruise the septum while the palate is securely retracted. The slide is held in position by the pressure of the retracted palate. The second instrument is a modification of the Sajous cold-wire snare. The modification consists only of the removal of the grooved duck-bill end, so that

a simple tongue and cannula remain. This tongue, being armed with a wire loop one to two inches in diameter and the ends bent forward and drawn backward into the cannula, which effectually prevents them from slipping, the operator is enabled to use the instrument repeatedly without changing the wire. These two instruments are especially effective for the removal of all naso-pharyngeal growths, adenoids, etc. With the aid of the rhinoscopic mirror and tongue depressor the wire can be made to encircle and remove a growth in any situation with comparative ease. Messrs. Meyrowitz & Co., of this city, have made the present models.

Dr. CASSELBERRY: Concerning the microscopic examinations of nasal polyps, I think that Dr. Wright has confirmed to a large extent those facts which we have already accepted; but one feels a sense of satisfaction in having such a confirmation from a man of known reputation in this line of work.

Concerning the clinical aspects of his paper, he touched upon one point about which I have had occasion to write, and that is, the removal of the anterior end of the middle turbinated bone as a means of access to the point at which these growths most frequently take origin—namely, the hiatus semilunaris or the edge of it. I do not mean to say that all myxomata take origin here, but I have had occasion to confirm the observations of Zuckerkandl, who asserts that at least two thirds of these growths are located in the region stated, and are therefore inaccessible, practically, so long as the turbinated body remains in its usual position. I do not intend to assert that it is possible in all cases to remove the anterior end of the turbinated body in order to gain access to this region, or that it is best to do so even in the majority of cases; but I have reported some cases in which this was possible and in which no deleterious results came from it. Some of these cases were not absolutely cured, but I was able to keep the growth under control, having gained access to this particular locality.

I understand that this discussion also includes Dr. Johnston's paper, relating to a case of nasal polypus projecting into the naso-pharynx. I was very much interested in the specimens he exhibited. I have in several instances had considerable trouble in passing the wire around myxomata which grew backward in this direction. I can not recall any case in which the growth reached the size of the one shown by Dr. Johnston. In some cases I have been able to pass a cannula such as Dr. Porcher exhibited behind the velum, so as to catch the polypus from the rear; at other times I have been able to reach it with the aid of cocaine contraction after the patient had violently blown his nose, so that the growth protruded forward, thus enabling me to catch it from in front. The removal of these growths demands the greatest skill.

Dr. WRIGHT: In reply to Dr. Mulhall's statement that atrophy is not consequent to hypertrophy, I can only say that it opens a large field for discussion. My opinion regarding this matter, which may be changed by future observation, was gained from a careful microscopic examination of numerous microscopic sections of nasal growths; these investigations led me to the conclusion that in the large majority of cases atrophy is preceded by hypertrophy. The sections were not only examined in cases of polypi, but in conditions bordering upon that. There are many grades of hypertrophy. That the terms *cirrhotic* and *atrophic* are not interchangeable is, of course, admitted. In the atrophy which takes place in the fibrous structures the fibrous tissue is the last thing to disappear. But finally that atrophies also, and if you examine a number of cases, in some you will find the mucous membrane so thin that you can feel the bone directly underneath the mucous layer.

As regards Dr. Casselberry's suggestion to remove the anterior end of the middle turbinated bone, in order to gain access

to these growths, I would say that in most cases I am unable to do it. In many cases the outline of the bone gradually slopes from before backward and downward, and I know of no instrument which will enable us to remove it; no snare will grasp it. I have often found this difficulty almost insurmountable. I myself have been very unfortunate in my attempts to remove the anterior end of the middle turbinated, but perhaps Dr. Casselberry has run across a more favorable set of cases, or perhaps he has unconsciously exaggerated the number of cases in which it is possible to follow out his suggestion. Or possibly my own experience has been the exceptional one.

The size of the polypus removed by Dr. Johnston is very remarkable. I removed one a few weeks ago that existed twenty-four years, curled up in the nose. Before it was put into alcohol it measured five inches in length.

Two Cases of Nasal Tuberculosis.—Dr. JOHN W. FARLOW, of Boston, read the histories of two cases. (See page 525.)

Dr. DE BROS: I think the time has gone by when tuberculosis and lupus were regarded as different and distinct affections. Lupus is nothing but a slow form of tuberculosis. I have always believed them to be identical. The occurrence of tuberculosis in the nose, and in that organ alone, I have never met with; this is the first case I have heard of. A tuberculous process extending from the mouth to the nose is comparatively common. I have seen two or three cases myself in which the tubercular ulceration probably extended from the hard palate up into the nasal cavities. They were all of the proliferative species, and were on the septum rather than on the turbinated bones. I regret to state that I can not report the good results of treatment which Dr. Farlow has obtained. I have always seen temporary amelioration, but the last stage would be worse than the first. I have in my mind a case I saw about two months ago in which the ulceration appeared first on the septum; the growth was cauterized and lactic acid applied, but it extended to the alæ of the nose. The patient is not dead yet, but the relief she obtained from the treatment was only temporary.

Dr. WRIGHT: It seems to me that in a case like this, unsupported by the presence of the tubercle bacilli, we should have to hold the diagnosis somewhat in abeyance. In the scrapings from such a growth in the nose it is rare to find the tubercle bacilli, but if you examine a number of sections of tissue from a tuberculous mass you are sure to find the bacilli. There are a great many forms of chronic inflammation which produce giant cells. A number of cases of tuberculosis of the nose have been reported abroad. Nevertheless, without the tubercle bacilli, I think the diagnosis in the cases reported by Dr. Farlow should be held back, especially where the lesion occurred on the turbinated bodies. In most of the cases reported the lesion occurred on the septum.

Dr. BEYAN: About two years ago I had an unusual case in which the primary tubercular lesion was in the post-nasal space. There was a profuse secretion of mucus, especially from the right side of the nose. The ulcerations increased in size, and extended down along the posterior palatine fold. During the course of the disease a swelling presented itself on the left side of the cartilaginous septum. The scrapings from the posterior nasal space, and also those from this swelling, gave a large number of tubercle bacilli. This patient has entirely recovered under local applications of strong solutions of lactic acid and the use of the curette.

Dr. CASSELBERRY: It would seem to me difficult to distinguish primary nasal tuberculosis from primary lupus of the nasal mucosa; and lupus involving the interior of the nose is not uncommon. Etiologically the two conditions are seemingly identical, yet clinically lupus assumes a different course, which would suggest at least a modification of the typical tu-

berculous process. An interesting case of mixed infection came under my observation a few years ago. The patient, a woman, had tubercular infiltration of the upper lobe of the left lung of some years' duration. She acquired syphilis and I treated her for typical primary and secondary symptoms, and for the early tertiary symptoms. About two years after the appearance of the chancre there appeared first within the vestibule of the nose a papular eruption with diffused infiltration, which later extended to the septum and turbinated bodies; while not then actually ulcerated, there was an eroded condition which resisted all attempts at treatment. Gradually the external nasal appendage also began to swell somewhat, and took on a reddish hue. Under the assumption that the condition was syphilitic, the patient was sent to Hot Springs, where vigorous antisyphilitic treatment proved of no avail. The nasal disease became worse. When she returned the lesion had distinctly the appearance of lupus and was so pronounced by several competent dermatologists. Subsequent events have abundantly confirmed this diagnosis.

Dr. MULHALL: In the first case reported by Dr. Farlow no tubercle bacilli were discovered; therefore there is no legal evidence of tuberculosis. Ulcerative lesions of the mucous membranes in my experience, even of a specific nature, are commonly made worse by the use of mercury. Furthermore, it seems somewhat suspicious that this patient was able to take sixty grains of potassium iodide, three times daily, without iodism and not be a syphilitic.

Dr. FARLOW: Under the supposition that the lesions might be syphilitic, the patient was put on "mixed treatment" for a time; potassium iodide, in increasing doses, forty or fifty grains, three times daily, and a quarter of a grain of the proto-iodide of mercury. She took these large doses for a limited time only.

In my paper I said nothing about treatment or prognosis. I simply reported these two cases, which presented sufficient evidence to me to warrant the diagnosis of tuberculosis. In the second case no tubercle bacilli were found. The patient had been under the care of Dr. White for some months, and his decided opinion was that it was not lupus. Dr. Whitney and Dr. Councilman said there was no question about the tubercular nature of the growth, even in the absence of the bacilli.

As regards the use of the curette and lactic acid in these cases, I did not express any opinion as to their value. I hold out no hopes of an absolute cure. Cases of tuberculosis of the nose, however, have certainly been reported in which the patients have lived for thirteen or fourteen years after operation without any return of the lesion. Cases of tuberculosis affecting the septum, in which the bacilli were found, have also been reported. My case was so similar to these, although the bacilli were not found, that I think I am justified in considering it tubercular.

Dr. RICE: Perhaps an interesting clinical fact in connection with this discussion is worthy of mention. When we were all using Koch's tuberculin we had under treatment at the hospital cases of laryngeal tuberculosis pure and simple, and two cases which were stated by Dr. George H. Fox and others to be true lupus of the skin. In one of these the lesion involved the entire integument of the nose and extended into both nasal cavities. In another case, one of tuberculosis of the larynx, there was a spot of ulceration on the side of the nose as large as a penny. All of these patients were given injections of Koch's lymph, and while hardly any benefit was obtained in the case of true laryngeal tuberculosis, the two other cases of lupus were markedly improved by the injections. The extensive ulceration on the integument of the nose in one of these cases of lupus was completely healed by these injections.

It is generally admitted that lupus is a form of tubercular disease, but tuberculosis laryngis and lupus laryngis certainly behaved very differently under the influence of injections of tuberculin.

Dr. F. I. KNIGHT: I should like to narrate the subsequent history of a case which I reported to this association at the first meeting in Philadelphia as a case of lupus beginning in the larynx. Although I am fairly well convinced as to the identity between lupus and tuberculosis, yet the appearances and the clinical history of those cases which we used to diagnosticate with a good deal of certainty as lupus of the larynx or pharynx, as distinguished from tuberculosis, are well marked. One of the cases I reported was that of a girl who had the peculiar thickening and ulceration of the epiglottis which from its history I concluded was lupus—not the tuberculosis of the larynx. Subsequent events showed that the diagnosis was correct. She never had lung disease, but lupus of the nose and face finally developed, so that there was really no question as to the correctness of the diagnosis. That girl was put in the winter of 1891 and 1892 under the most rigorous tuberculin treatment, which resulted in only a very slight amelioration of the skin trouble. She went through a long course of it and finally gave it up and in a few weeks was worse off than before. In that case the tuberculin had no such marked benefit on the lupous lesions as it had in Dr. Rice's cases.

Dr. SWAIN: I should like to relate a case of interest in relation to the cure of local tubercular lesions. The case came up, as did those of Dr. Rice and Dr. Knight, in connection with the use of tuberculin. The patient, when she was about fourteen years old, had been "given up" to die of consumption. She suffered from cough and wasting, and had all the symptoms we are so familiar with. In addition to that, she had local trouble in the larynx. I saw the case later, after the whole process had come to a standstill, and found that the tuberculous process had involved the epiglottis, the epiglottic fold, and a portion of the anterior pillar of the soft palate. The case was treated by the family physician with the view that the lesion might be syphilitic and with no result. He then cauterized it with nitrate of silver, I believe, and with a change of climate the patient completely recovered. Seven years later she had lupus of the nose, as diagnosticated by Dr. Fox, which was treated by him by cauterizing each individual nodule with the actual cautery, plunging a red-hot needle into the tuberculous collection, which caused very little disfigurement. This method of treatment was abandoned when Koch's lymph came out, and she was treated by means of that for eight or ten weeks. We got the typical reaction throughout the entire local lesion, and, what was more interesting, also in the line of the old scar around the epiglottis and the aryteno-epiglottic fold. The tuberculin treatment resulted in no permanent good to the lupus. New nodules formed, and the patient is at present again under treatment by Dr. Fox. There is still some comeliness of the nose, although the outer rim and the septum are involved. I offered to treat her by scraping and lactic acid, but she prefers the old treatment.

Dr. GLEITSMANN: I wish to say that when the lactic-acid treatment was recommended I was one of the first who made extensive experiments with it in one of my clinics at the German Dispensary, and the results of these experiments were published. About that time I had a patient suffering with primary tuberculosis of the larynx. The patient was treated successfully by means of lactic acid, and was shown at the section meeting of the academy; I also related the case in Berlin three years ago. The lesion was an extensive one—so much so that I was almost disheartened. The treatment consisted in scraping the ulceration and rubbing in the lactic acid. The patient was

reported well three years ago, and remained so up to this year. In February last another ulceration appeared at the site of the original lesion. It healed under a similar mode of treatment and the patient has remained well up to the present time.

I wish to add that I have complete faith in the local surgical treatment of the upper air passages in these cases: that is, scraping, the actual cautery, and the application of lactic acid.

Dr. WRIGHT: I have employed this method of treatment in a number of cases, but only in one case have I seen benefit derived from it. For a time I was quite enthusiastic on the subject, but so many failures followed its use that I fell back into my original slough of despair. I recently saw a case of tubercular ulceration of the epiglottis that had been under treatment at the German Dispensary. I scraped the growth and applied lactic acid, with the result that the previously painless ulceration has spread rapidly and become very painful.

NEW YORK STATE MEDICAL ASSOCIATION.

Tenth Annual Meeting, held in New York on Monday, Tuesday, Wednesday, and Thursday, October 9, 10, 11, and 12, 1893.

The President, Dr. S. B. WYLLIE McLEOD, in the Chair.

(Concluded from page 482.)

The Surgical Treatment of Pulmonary Cavities.—Dr. N. P. DANBRIDGE, of Cincinnati, read a paper in which he said that previous attempts to disinfect the secretions found in pulmonary cavities had, as a rule, proved ineffectual. A French writer had reported a case in which the consolidated apex of a lung had been successfully removed from a man twenty-five years of age, but such exceptional cases, while interesting as curiosities, furnished no rule for our guidance. To practice such operations one must ignore all the acquired knowledge of pathology.

The cases in which surgical treatment might be employed to advantage in the treatment of pulmonary cavities might be divided into two classes—viz.: 1. Abscess of the lung, pulmonary gangrene, and hydatid cyst. 2. Tubercular and bronchiectatic cavities. Where tubercular cavities were quite superficial and confined to one side, and the secretion was very free, it would seem that external drainage offered a good prospect of success.

The author then related the history of a case in which he had operated. The patient was a fairly well nourished but alcoholic subject, twenty-nine years of age, having a decidedly phthisical family history. He complained of severe pain on the right side and of constant dry cough, and his temperature was 99° F. The cavity having been properly located by the physical signs, three inches of the eighth and ninth ribs in the axillary line were removed, and the underlying cavity was freely opened. It reached to the surface of the lung, and its walls were rough like those ordinarily seen in phthisical cavities. About half a pint of blood-stained fluid and some debris were removed; the cavity was washed out with sterilized boric-acid solution, and a drainage-tube inserted and allowed to remain for several days. His general condition improved rapidly, and he was discharged from the hospital in about two months. This case showed the type most favorable for the operation. The operation was undoubtedly often undertaken under the mistaken notion that the operator was dealing with a localized empyema. Statistics were quoted to show that the operation was simple and comparatively free from danger.

In the majority of cases of bronchiectasis the dilations were so numerous that little good could be expected from such treatment, but occasionally there were cases in which there was a single large cavity which was evidently chiefly respon-

sible for the bad symptoms; under such circumstances the operation was indicated, although it was more dangerous in this class of cases than in that already described, because the cavities were not usually so superficial.

In cases of gangrene, abscess, and hydatid cyst surgical writers now inclined to the opinion that an attempt should be made to open and drain the cavities whenever they could be properly located. After incision, the cavities were best treated by packing with iodoform gauze. It was important to determine in all cases whether or not adhesions had taken place between the pleura and the chest walls, for the danger of the operation was greatly enhanced by cutting through normal lung tissue. The quantity of discharge from the mouth was said to be no indication of the size of the pulmonary cavity. A large aspirating needle should be first introduced to determine if possible the location and depth of the cavity, and this procedure should be repeated at the time of the operation. The needle could then be used as a guide for the knife.

This paper was considered in connection with the following:

A Discussion on Lesions of the Pleura.—Dr. JOHN SHRADY, of New York County, opened the discussion, propounding the following questions:

Question 1.—What are the factors of pleurisy? What are its forms and contributive conditions? What are the pathological changes in a case of progressive pleurisy ending in recovery?

Question 2.—What are the points of diagnosis in pleurisy and other affections of the chest?

Question 3.—What is the treatment of empyema, with the relative value of aspiration, rib resection, and free opening with tube drainage?

Dr. Shradý said that cold, wet, and traumatism must be considered the chief ætiological factors. The shifting line of dullness in the upper part of the cavity was the key to the diagnosis. Aspiration would usually determine the traumatic nature of a pleurisy by withdrawing bloody serum. Peritoneal and pericardial complications indicated tubercular origin, and secondary pleurisy foreshadowed the probable occurrence of pyopneumothorax. The indications for treatment were to limit the exudation in the early stage, allay pain, relax the bowels, reduce fever, and, later on, promote absorption of the effusion. These were substantially Osler's recommendations. When there was sufficient fluid to produce intermittent orthopnea, when the fluid half filled the chest cavity, when it showed no sign of absorption after a month, and in all cases where there was a purulent effusion, we should aspirate. These were the common-sense and practical rules laid down by Dr. R. C. M. Page. The point of election for thoracocentesis was the sixth intercostal space, close to the upper border of the seventh rib and along the axillary line. In empyema, the center of infection might be outside the pleura, as when it occurred in pyæmia and puerperal septicæmia. In adults it was generally due to pulmonary tuberculosis. It should be remembered that, unless some of the pus was absorbed into the system, its presence might easily be overlooked, and we might explain the fluctuations of temperature by tubercular infection. If there was not sufficient room for drainage after making a simple incision, a portion of the lower rib—not necessarily its entire width—should be excised and a drainage-tube without lateral openings inserted and stitched to the skin. The after-treatment consisted in washing out the cavity with weak antiseptic solutions.

Dr. WILLIAM MCCOLLUM, of King's County, replied to the first question. He said pleuritic adhesions or exudates were found in about half the subjects examined post mortem. Pleurisy was oftener of tubercular origin than previous teaching had

indicated, and the streptococcus, staphylococcus, and pneumococcus had an important ætiological relation to this disease. The streptococcus was oftener present in adults, and the pneumococcus in children. The diversity of opinion regarding the causal relation of pathogenic microbes to pleurisy might be explained partly by the different stages at which different investigators had made their observations, for it was well known that the serous exudate gradually changed to a purulent one. It must also be remembered that the pneumococcus had a brief life, and therefore, in cases in which it had been reported as absent, it might have been present previous to the time of the recorded observation.

Dr. J. BLAKE WHITE, of New York County, replied to the second question. He said that the local pain was not characteristic of pleuritis, although certain peculiar manifestations might aid in making the diagnosis. The pain was sometimes referred to other parts—*e. g.*, the abdomen. In tubercular pleurisy the important symptoms were cough, pain in the side, and dyspnea, and they were developed in this order; but in other pleurisy these symptoms were in a different order—*viz.*, pain in the side, dyspnea, then cough. In the diaphragmatic form the existence of digestive disturbance and hicough might aid us. The tendency to clear the throat when there was no lesion of the throat was quite characteristic of pleurisy with adhesion. A useful point which he had not seen mentioned was that a short, dry cough pointed to adhesions high up in the chest, whereas a prolonged cough pointed to adhesions lower down in the chest. The pericardial friction sound was distinguished from the pleural friction sound mainly by difference in rhythm; a change of sound from the ordinary friction to creaking was far commoner in the pleura than in the pericardium. The writer asserted that, although no one doubted the existence of microbes in pleuritic exudates, no investigation had yet proved their causal relation to pleurisy. Tuberculosis formed the strongest argument for its microbic origin, yet he was a poor diagnostician who waited for the microscope to make the diagnosis.

Dr. J. G. TRUAX, of New York County, also replied to the same question. He said that the friction sound, or pleuritic r le, was not generally heard over a large part of the chest wall, and was seldom present long in any one spot, as it changed with the extension of the inflammatory process. The friction could be felt as well as heard by placing the hand flat on the chest-wall. Sometimes deep inspiration was requisite to elicit the sound, which was most commonly heard in the axillary region or below the nipple. It was audible a few hours after the beginning of the pleurisy, and might last for weeks. To an unpracticed ear this sound would often be overlooked or mistaken for bronchial crepitation.

Dr. CHARLES A. LEALE, of New York County, responded to the third question. He referred to a boy in whom, through the hearty co-operation of the parents, he had been enabled to bring about a complete restoration of the lung and pleura after an empyema without resort to operation. The treatment had extended over a period of two years, and the lung and pleura had been found in normal condition after about five years. Of course, if less favorable conditions had been present, such a result could not have been obtained. Those who favored free incision into the chest should have seen an army officer who had come under his observation during the late war with a terrible gaping wound in the chest. He thought any one who heard this man's piteous appeals to have this opening closed, so as to relieve him of the intense and constant pain, would not attempt to imitate in the name of surgery the frightful act of war.

The writer also cited a case in which a healthy, robust man

had contracted pulmonary tuberculosis from his wife and become affected with empyema. After a sojourn in Egypt for many years he had returned in such good health that he scouted the idea of his ever having had consumption, yet the necropsy on this man had shown all the signs of cured consumption. It had also shown that if the pus had been removed from his thorax it would have interfered with the thick, elastic covering over the diaphragm which Nature had placed there as a barrier to the spread of the disease.

Dr. THOMAS H. MANLEY dwelt upon the dangers of aspirating the chest, and stated that not one of his patients that had been treated in this manner had lived more than three years.

Dr. CROVYN said he was sorry to hear the use of the aspirator decried in this manner, for he was accustomed to use it early in all cases of pleurisy with effusion, and he had never seen anything but good follow this treatment. He held that pus, as such, could remain in the pleural cavity for an indefinite time without doing any harm; it was the absorption of septic pus that was dangerous. He was not in favor of resecting ribs in operating for empyema, because it was unnecessary. He would treat acute pleurisy with dry or wet cups, followed by a brisk purgative, and then with opium. The speaker then referred to the cure of pulmonary tuberculosis by metastasis, and narrated the history of a case in which a man suffering from tuberculosis of the lungs had been cured of this affection by an attack of acute mania.

Dr. FERGUSON said that, as a rule, incision and drainage in empyema effected a cure. In exceptional cases, where one was fortunate enough to diagnose a localized empyema, this could be cured by aspiration.

Dr. DONALD McLEAN, of Detroit, said he had for a long time almost abandoned the aspirator except in rare instances as a means of diagnosis. With this instrument one rarely succeeded in completely emptying a cavity. Resection of the rib he looked upon as fulfilling one of the most important rules in surgery—the establishment and maintenance of free drainage.

Dr. DANDRIDGE said it was very exceptional for him to treat empyema without resection of the ribs. Aspiration had, however, the advantage over the opening into the chest that it maintained the negative pressure and so materially assisted the expansion of the lung.

Remarks on Fermentative Dyspepsia.—Dr. AUSTIN FLINT, of New York County, read a paper on this subject. (See page 425.)

Dr. CROVYN thought that in the class of cases in which the subgallate of bismuth acted so well there was a lack of hydrochloric acid in the stomach, and that the administration of this acid would probably have yielded much the same results. Fermentative dyspepsia was often perpetuated by a too prolonged use of some specially restricted diet.

Dr. HENRY F. RISCH, of Kings County, said that in the treatment of these cases his first effort was to determine whether the fermentation was due to the decomposition of hydrocarbons or nitrogenized substances, and then, having ascertained this, the offending class of food-stuffs was excluded from the dietary.

Dr. LEALE spoke of the excellent results which had been obtained at St. John's Guild Hospital last summer by a resort to lavage of the stomach and bowel. Having once cleansed the intestinal canal, remedies such as the trinitrate of bismuth and Fowler's solution were given.

Bloodless Amputation at the Hip Joint; Report of Cases of Operation by the Author's Method.—Dr. JOHN A. WYETH, of New York County, gave a historical sketch of the various methods that had been resorted to for controlling hemorrhage in amputation at the hip joint. As long ago as 1855

there had been a description in the *American Journal of the Medical Sciences* of a method devised by an American surgeon in which the vessels were controlled by acupressure. In 1890 he had first successfully applied his method in an amputation at the hip, and shortly afterward he had demonstrated it before a number of medical societies. He gave in the paper in brief the histories of thirty-nine amputations which had been done by his method. These operations represented the work of a large number of operators of all grades of skill and experience, yet the statistics were extremely favorable as compared with those of other methods. In thirty-five cases the amputation had been performed for disease, and in four for injury. Of the former, five patients had died, a mortality of fourteen per cent.; of the latter, all had died. These had been cases of unusually severe and extensive injuries, and could not be considered as in any way arguing against the value of the method.

Dr. JOSEPH D. BRYANT, of New York County, said the paper spoke for itself and made it clear that the profession was deeply indebted to the author for making known this bloodless amputation at the hip joint.

Dr. McLEAN said he appreciated the value of the method, but he should not be true to his own convictions and experience if he did not state that he thought his method of compressing the abdominal aorta was still better.

Dr. REGINALD H. SAYRE, of New York County, said that his only two amputations at the hip joint had been done before the publication of Wyeth's method, but from the description of the method he should be inclined to think that in some cases the elastic ligature would be apt to encroach upon the field of operation.

The Code of Ethics.—Action was taken with reference to the question of the advisability of amending the code of ethics. The following was ordered to be sent to the American Medical Association in answer to its letter of inquiry:

"In reply to the notice that the American Medical Association had requested the State medical organizations in affiliation with that body to express their wishes in reference to any changes in the code of ethics, the New York State Medical Association has to state that it has made that code one of its foundation stones, and that it is entirely opposed to any alteration therein. This is the result of a full reconsideration of the subject, and after an experience of ten years of organization under the code."

Treatment often indicated after Trachelorrhaphy.—Dr.

WILLIAM H. ROBB, of Montgomery County, read a paper with this title. He said that the treatment required after this operation might be divided into general and local. In addition to the hygienic treatment, which was extremely important, the general treatment included the administration of medicines. He had obtained especially good results from the use of mercury and iodide of potassium. The former unloaded the portal circulation; the latter acted as an alternative on the uterine tissue. The persistent use of such local measures as leeching, scarification, and puncture of distended cervical glands often sets up a process which would eventually terminate in recovery. Chronic endometritis was the most common complication met with, and it was best treated by dilatation of the cervix, curetting, and drainage of the uterus. Where there were inflammatory deposits and adhesions, skillful galvanic treatment would usually effect a cure; but where this failed, abdominal section was the proper alternative. Imperfect union of the torn surfaces of the cervix after trachelorrhaphy sometimes caused chronic enlargement of the uterus. This might be due to incomplete coaptation of the flaps or to drawing the sutures too tightly.

Dr. A. PALMER DUDLEY, of New York County, said that

much of the treatment which was often left undone until after a trachelorrhaphy should really have been done before the operation; indeed, the operation might not then have been required. He did not approve of the term "areolar hyperplasia," for the reason that the areolar tissue which was supposed to develop after delivery he believed was put there by Nature previous to the completion of gestation, and, as a result of sepsis or congestion, it had not been removed when it was no longer needed. Hence the term subinvolution was more appropriate. Where there was congestion or tenderness of the cellular tissue he did not resort to trachelorrhaphy until after the endometrium had been brought to a healthy condition by division, curetting, and packing. When he performed the operation, he purposely cut the circular artery, and allowed several ounces of blood to escape, and then the main branches of both uterine arteries were ligated so as to "starve" the uterus for a time. In this way the uterus might be rapidly reduced in size. It was proper to examine the cervix immediately after labor, and, if lacerations were found, to repair them at once with catgut.

Dr. FERGUSON thought that there would be some difficulty in determining the existence of a tear at this time, or, at any rate, in determining its limits, particularly in primiparae.

Dr. ROSS said that cleanliness alone was sufficient to cause many minor lacerations to heal without operation; hence the immediate operation was not demanded in many cases.

Voluntary Commitment of the Insane to Asylums.—Dr. W. D. GRANGER, of Westchester County, read a paper in which he said that the central idea of asylum care to-day was the preponderance of medical supervision and individualization of the treatment. The exercise of liberty and the consequent development of self control were important factors in this treatment. Voluntary commitment was desired by a certain class of the insane, and several States had enacted laws governing such commitments. These persons were usually committed for a certain short period, and were to be discharged on a written notice being given. The great defect of this system was that after commitment these patients were treated about the same as those in the asylum who had been involuntarily committed; they were deprived of their liberty. To obviate this, the Commissioners in Lunacy in New York State had devised a plan of commitment to family asylums for no specified time, the patient being allowed to leave whenever he desired to do so. It was expressly stipulated that no person should be voluntarily committed who was in such a condition as not to appreciate fully what he was doing. These asylums were visited by the commissioners, and they had a right to discharge those who might have been committed in this way who they thought had not thoroughly comprehended the meaning of their commitment.

Dr. ELIAS LESTER, of Seneca County, said this method of commitment ought to prove very useful, especially in those rather numerous instances in which it was very difficult to decide at once whether or not the patient was really insane. In his vicinity, however, the law had been made very obnoxious; he was not positive whether this was due to imperfections in the law itself or to the capriciousness of the authorities at the asylum.

The Treatment of Typhoid Fever.—Dr. GUSTAVUS ELIOT, of New Haven, Conn., read a paper in which he said that, as absolute quiet and rest in bed were essential to the safety of the typhoid-fever patient, it should be the rule in every case of fever where there was a possibility of its proving to be typhoid to exclude this disease before allowing the patient out of bed. Neglect of this precaution had caused many deaths. This condition of quiet, both of body and of mind, must be maintained until both the morning and evening temperature had remained

for at least a week below 99° F. The writer believed that the calomel treatment had given the best results, and he advised the administration of from seven to ten grains on alternate days until four doses had been taken. The sooner this was done the better. The calomel usually produced easy and moderate evacuations of the bowels, and by removing fecal matter, bacteria, and ptomaines, acted as an intestinal antiseptic. Iodine and carbolic acid were both sedative to the stomach when given in dilute form, and their administration in enteric fever along with the calomel treatment, as just described, seemed to improve all the symptoms and shorten the course of the disease.

Dr. GEORGE DOUGLAS, of Chenango County, said he had been particularly pleased with the emphasis that had been laid on the importance of absolute rest—a fact difficult to impress upon the laity. It was useless to administer medicines with the object of aborting the fever, but where there was much diarrhoea it would be found advantageous to give creasote in a weak solution of magnesia. He would not care to give the calomel more than three times, and sometimes he would prefer to substitute a dose of magnesia for the third dose of calomel. He did not approve of the early or free use of alcoholic stimulants.

Dr. WILLIAM FINDER, of Rensselaer County, believed that in the early stage the quantity of food given should be small. The mineral acids, particularly dilute phosphoric acid, were useful, and he had unbounded faith in sulphocarbolate of zinc as an antiseptic and astringent.

Dr. ELIAS LESTER, of Seneca County, said that there seemed to be a strong malarial element in all the cases occurring in his part of the State, and that therefore he found it absolutely necessary to administer quinine.

Dr. JOHN H. MARTIN, of Otsego County, was heartily in favor of a few doses of calomel at the outset, and after this he gave Lugol's solution of iodine or, if the intestinal symptoms were marked, oil of turpentine. He fed his patients well from the beginning. He was entirely opposed to the use of alcohol in typhoid fever.

Dr. E. R. SQUIBB, of Kings County, thought the chemistry of calomel, when introduced into the body, would throw light upon its action in typhoid fever. When calomel was taken into the body it was converted into an albuminate, and this, in turn, was slowly converted into the bichloride of mercury; hence it was probably largely because of its antiseptic properties that it had proved so useful in this disease.

Rare Forms of Gout and Rheumatism.—SIR JAMES A. GRANT, of Ottawa, Canada, read a paper in which he described in detail the histories of three or four interesting cases of gout and rheumatism that had presented unusual manifestations. In one case, which he had diagnosed as rheumatic perityphilitis, a young girl presented all the usual symptoms of perityphilitis for some days, and then suddenly became affected with well-marked symptoms of acute articular rheumatism in the joints of the upper extremities. At the same time the abdominal symptoms began to improve very rapidly. The fact that errors of diet so frequently acted as predisposing causes of rheumatic attacks led one to the belief that the theory that rheumatism was due to defective assimilation and excretion was probably correct. Haig, of London, believed in rheumatism and gout affecting the walls of the intestines. While gout was almost unknown in Canada, rheumatism was quite frequent, yet among the lumbermen, who were exposed to all the rigors of that trying climate, rheumatism was not very common, probably owing to the fact that they lived chiefly on pork, bread, and tea. Simplicity of diet explained their immunity from rheumatism.

Surgical and Pathological Memoranda was the title of a paper by Dr. DONALD McLEAN, of Detroit, who described a

number of interesting cases occurring in his practice, and laid down the principles which had guided him in treating them.

He had had an unusual number of ununited fractures of the long bones, and had found it necessary in some cases to resort to amputation. He had come to the conclusion that the commonest cause of non-union of fractures was excessive violence at the time the fracture was produced.

In cases of amputation at the thigh, he was strongly in favor of using the abdominal tourniquet or aortic compressor. The instrument should be placed over the umbilicus, with an intervening pad. Not only did it very thoroughly control the hemorrhage, but after the limb had been amputated the process of securing the vessels was greatly facilitated by releasing the pressure very slightly, and thus allowing the escape of a few drops of blood.

He had successfully treated two cases of spina bifida by injections of iodine and subsequent amputation.

In two cases of painful tumor of the median nerve he had excised the tumor with complete relief. One of the tumors was exhibited.

Discussion on the Treatment of "Appendicitis."—Dr. FREDERICK S. DENNIS, of New York County, opened the discussion, propounding the following questions: 1. What proportion of cases of appendicitis end in resolution? 2. What cases require immediate operation? 3. What cases do not require immediate operation? He said that there were several different varieties of inflammation in the region of the cæcum, and there was no reason why ordinary inflammation in this region should not undergo resolution as well as elsewhere. It was now pretty generally accepted that about fifty per cent. of cases of inflammation in this region went on to resolution, and only about eleven per cent. were relapsing. Where there were a rapid pulse, suppurative temperature, and intense pain, and there was no abatement after forty-eight hours, it was proper to operate, but he did not approve of operative interference unless the symptoms were urgent. The operation itself was not trifling, the length of the incision made ventral hernia a very common sequela, and there were many cases on record of errors in diagnosis made by eminent practitioners.

Dr. JOHN W. S. GOULEY, of New York County, said he fully agreed with the writer's views on this subject. Since the publication of Dr. Willard Parker's paper he had observed twenty-four cases of appendicitis that had ended in resolution. He had recently seen a patient who had been sent to hospital for operation; yet, after making a careful examination and confirming the diagnosis, he had refused to operate and the patient had recovered completely. While an operation was not required in at least half the cases, there were instances in which very prompt surgical interference might save life. For example, a few years before, he had seen a young gentleman who five days before, while dancing, had been seized with such severe pain in the right iliac region that he had had to be taken to bed. When first seen he was almost moribund. The autopsy showed general peritonitis and perforation of the appendix vermiformis.

Dr. McLEAN said that the questions propounded here for discussion were among the most difficult of those which confronted the surgeon, and no one practitioner's experience could justify a positive answer to all these questions. The speaker then narrated a number of interesting cases illustrating the difficulties of the subject. A young man of delicate constitution had symptoms of acute appendicitis—sallow complexion, rapid pulse, moderate fever, and local pain. Being loath to operate on such a subject unless it was absolutely necessary, the speaker had decided to wait for twenty-four hours. At the end of this period there was slight improvement, and the patient

ultimately recovered without surgical interference. In another case—one of recurring appendicitis which he had seen in consultation—both physicians had agreed that the time had come to operate, so the operation was performed with every precaution known to surgical science, yet the patient lingered in agony for twenty-four hours and died. There must have been in this case a secondary reservoir of pus which spread the infection. He could recall having seen during the past two years quite a large number of cases in which, notwithstanding that the symptoms were urgent, the patients had recovered without an operation.

Dr. JOSEPH D. BRYANT, of New York County, said that, in about seventy per cent. of males and forty per cent. of females, a foreign body might be found in the appendix, and this was about the relative frequency of appendicitis in the two sexes. Fitz had shown that fifty per cent. of fatal cases examined showed perforation of the vermiform appendix. If perforation had occurred, the symptoms would be very acute in almost every instance, and indicate the necessity for immediate operation. The "McBurney point" could not be considered as pathognomonic, for, aside from the fact that it had been found under other conditions, it was evident, from the great variation in the position of the caput coli, that no such fixed point could represent the position of this part of the bowel in any large number of cases. Neither was the presence of a tumor of much assistance in making the diagnosis, for in fourteen per cent. of the cases the vermiform appendix extended into the pelvis, in about twenty per cent. it was behind the caput coli, and in two per cent. it was high up behind the colon. If the fever, tenderness, and tympanites continued after three days, and especially if there was rigidity of the rectus muscle, he would advise an operation.

Dr. J. A. WYETH, of New York County, heartily indorsed the position taken by the preceding speaker; if one was in doubt it was much safer to err on the side of an exploratory operation. All the disasters he had seen in the surgery of appendicitis had been due to delay. Besides this, there was much less danger of ventral hernia following the early operation than the late one, for in the latter case it was necessary to allow the wound to heal slowly by granulation.

Dr. FERGUSON said that his surgical work had been done in private practice, yet, out of about twenty cases seen annually, not more than three or four had required operation. It was important to remember that when the appendix could not readily be found it was better to leave it behind.

Dr. CROXON narrated briefly the history of a case in which the signs and symptoms had pointed rather strongly to appendicitis, and after some delay an operation had been performed, but nothing found. On the fourth day after the operation something white was discovered at the bottom of the wound; this proved to be a piece of omentum, and on its removal the patient rapidly recovered.

The Male Catheter, with some Observations upon the Proper Mode of its Introduction into the Bladder.—Dr. DOUGLAS AYRES, of Montgomery County, in a paper thus entitled, considered it very important that one should bear constantly in mind the three great anatomical divisions of the urethra—viz., the prostatic, the membranous, and the spongy portions, and their respective lengths and diameters. He preferred in most cases to use a silver catheter, No. 9 or No. 10 of the American scale. This size corresponded most nearly to that of the average urethra, and consequently was less likely to be caught in the folds of mucous membrane than a smaller catheter. The various flexible instruments were very useful in some cases where the canal was tortuous, but he relied chiefly on the silver catheter, as he could much more easily determine

its exact position in the urethra and could therefore guide it more intelligently. In introducing the catheter, it should be kept in the median line and close to the surface of the abdomen until it entered the membranous portion, in order to avoid its engaging in the upper portion of the triangular ligament. The patient should be in the recumbent posture, with the thighs well separated and flexed and the shoulders moderately elevated. A hint worth remembering was that sometimes by pressing down the soft parts above the pubes the suspensory ligament would be relaxed and the introduction of the instrument thereby facilitated.

Dr. JOHN W. S. GOULEY then exhibited a bronze model of a catheter found in the ruins of Pompeii. It was interesting to note that it had the sigmoid form believed to have been first introduced about two thousand years later, that it had a distinctly conical shape, and that it had a single eye very near the vesical extremity. Dr. Gouley exhibited a number of catheters of domestic manufacture, and called attention to their fine finish, which, in his opinion, was much superior to that of the foreign instruments.

Researches on the Efficiency of Vaccinia after Typhoid Fever.—Dr. WILLIAM FINDER, of Rensselaer County, in a paper with this title, said that when vaccination was first introduced it was believed that one vaccination would protect the individual for an indefinite time. Although this was now known to be incorrect, we were still in the dark as to the number of years it would ordinarily give this protection against small-pox. Thus far the contagious principle of variola and that of vaccine had not been discovered.

From 1874 to 1880 small-pox had been almost constantly epidemic in Troy. At this time he had observed three persons who had had in childhood a slight attack of small-pox, and yet after vaccination they presented a beautiful pock. Inquiry elicited the fact that they had recently been ill with typhoid fever, and further observation showed that other persons who had been ill with typhoid fever were successfully vaccinated, while many individuals who had not had this fever could not be successfully vaccinated. From this he concluded that typhoid fever removed the protection afforded by vaccination. He had since had an opportunity of confirming this theory in other cases, but he had waited for years before publishing these observations, in the hope of having other opportunities for verifying them again. It was his practice now to revaccinate after typhoid fever.

Reflections on the Need of Close Observation of Disease and upon the Value of Hygienic Therapeutics.—Dr. H. ERNST SCHMID, of Westchester County, introduced his theme by several amusing anecdotes designed to show the importance of very minute observation. This was all-important to medical men, and explained the seemingly miraculous powers of some diagnosticians of note. Medicine was far from being an exact science, and there must be many roads leading to the same goal; the skill of the physician was shown in his selection of the road. Amid all these uncertainties physicians were often blamed, and even sued for malpractice, when a case did not turn out as satisfactorily as one might wish. Had a lawyer ever been sued or punished for losing a case? Yet the same law punished the physician for his mistakes. In closing, the author touched upon the relation between disease and the weather, and advocated a more general adoption of hygienic, dietetic, and hydropathic treatment.

A Case of Puerperal Blindness was reported by Dr. DARWIN COLVIN, of Wayne County. It had occurred in a woman who, in two or three previous pregnancies, had had edema, vertigo, and puerperal eclampsia. She had been under the care of another physician, so the advice of the writer had not

been sought until 1890, when she was again about seven months pregnant. The urine for the twenty-four hours did not exceed ten ounces, and it contained a large quantity of albumin. Literal venesection—twenty-four to thirty ounces—with the patient in the recumbent posture, followed by a hydragogue cathartic, was advised. The attending physician hesitated to bleed her, and there was a long delay, so that she had already become blind before this was done. Immediate improvement followed the venesection, and six days later labor occurred quite unexpectedly. It terminated without special complication, and the child was alive and healthy. Eleven days after confinement the author saw her, and found her still totally blind, and the urine still scanty and albuminous. This was in November, and it was not until the following March that there was positive evidence of improvement in her vision. After about a year her vision became fairly good, but not so good as before this pregnancy. The writer's conclusions were that, as she was a multipara, greater danger was to be apprehended in view of her previous history; that immediately after the occurrence of edema, and before the development of the eye symptoms, she should have been very carefully watched; that when the anasarca and cephalalgia were first observed free venesection should have been employed and the diet regulated; that shortly before the expected time of her confinement, if there was no improvement, another venesection would be imperatively demanded; and that, if it had not been for the venesection, she would have had eclampsia in this last labor, and probably the eye lesions would have been more lasting.

Dr. T. J. MCGILLICUDDY, of New York County, said he had seen five cases of blindness occurring with puerperal eclampsia. None of these patients had been bled, yet all had recovered perfectly after delivery. All these patients had been young women, and in all the blindness had come on just prior to or during the convulsions.

A Plea for the Non-operative Method of treating Dysmenorrhœa, Pelvic Inflammation, and Pelvic Abscess.—A paper with this title was read by Dr. T. J. MCGILLICUDDY, of New York County. (To be published.)

Officers for the Ensuing Year.—Dr. THOMAS D. STRONG, of Chautauqua County (fourth district), was elected president, and Dr. ISAAC DE ZOUCHE, of the first district, Dr. JOHN C. BENHAM, of the second district, Dr. HOMER O. JEWETT, of the third district, and Dr. JOHN D. RUSHMORE, of the fifth district were elected vice-presidents.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Nineteenth Annual Meeting, held in Indianapolis on Wednesday, Thursday, and Friday, October 4, 5, and 6, 1893.

(Concluded from page 513.)

SECTION IN GENERAL SURGERY.

Dr. W. N. WISHARD, of Indianapolis, Chairman.

Some Illustrative Cases of Nasal Headache.—A paper with this title was read by Dr. H. W. LOEB, of St. Louis, who, at the last meeting of the Missouri State Medical Association, had presented a paper upon nasal headaches in which the following list of such conditions was suggested as possessing an ætiological significance: Acute inflammations of the nasal mucous membrane, chronic rhinitis, rhinoliths and foreign bodies, septal deformities, deflections, spurs and ridges, diseases of the accessory sinuses, chronic atrophic rhinitis, and anything which caused the middle turbinate tissues to press against the septum. In headaches of the following characters, it was stated that a nasal origin might be expected: 1. Frontal headaches 2. Hemicrania starting about the orbit. 3. Long-continued

headaches. 4. Headaches of which successive attacks were identical or similar. 5. Headaches increased or originated by acute rhinitis. 6. Headaches associated with evident disease of the nose or accessory cavities.

In the present paper the author presented cases which illustrated the characteristics, both symptomatic and causal, stated in the before-mentioned contribution.

The Treatment of Fractures of the Leg.—Dr. J. T. BERGHOFF, of St. Joseph, Mo., in a paper on this subject, said that fractures of the leg should never be treated with the leg resting on the bedding, but it should be suspended. He cared not how well the surgeon might coaptate the broken bone and protect the same with splints and bandages or plaster of Paris; if the limb rested on the bedding, by each movement of the body of the patient the fracture was sure to move. The process of repair was exactly the same in soft tissues and in bones. Why did union by first intention take place? Because the lips of the wound were exactly coaptated, and kept so. The wound healed sometimes in three days, at the furthest in a week. But to put a broken limb in an immovable condition and keep it so without great suffering to the patient could not be done under the old system.

Dr. Berghoff then described an apparatus, or splint, the outgrowth of patient study for twenty years, but more particularly the last ten years. The apparatus was also adapted for treating disease of the hip, knee, and ankle joints, for the extension could be adjusted as the case required, the joints being kept immobile.

Incurability of Advanced and Extreme Cases of Talipes Equino-varus by the Means and Methods in Vogue at the Present Time; Suggestion of a Way to remove the Deformity without disturbing the Usefulness of the Extremity.—Dr. LOUIS BAUER, of St. Louis, presented a plaster cast of a talipes varus in which the weight of the body rested upon the dislocated astragalus and calcaneum. He produced also the skeleton of the leg and foot of a person who had died while in this condition. He showed that there was complete dislocation of the astragalus; that joint surfaces had formed between that bone and the calcaneum whereby the weight of the body rested entirely upon the end of the astragalus and calcaneum; and that the scaphoid and other bones of the foot bore little if any part in sustaining the weight of the body. It had been found impossible in extreme cases of talipes to restore the foot to its natural position by tenotomy or by *brisement forcé*. In one case, after six years' trial, the author had proposed an amputation similar to Chopart's whereby all the bones anterior to the astragalus were removed. The operation would leave a linear scar anterior to the astragalus in its new position and would be out of the way, and in such a direction the artificial foot could be easily adjusted. He had not had an opportunity of trying this method, but felt sure that this amputation was a proper method in cases where, after long-continued efforts, reduction could not be effected. He also reported a case where there had been extreme lateral curvature of the spine from distortion of the pelvis in a young musician. He had become satisfied that the deformity was due to the unnatural position, and had therefore directed a long splint applied reaching from the axilla to the foot, and the pelvis had gradually been pressed toward the splint by an appropriate bandage. After a period of time not stated by the author the patient had recovered.

Dr. MARSEE, of Indianapolis, took strong ground against tenotomy, tarsectomy, and amputation in these cases, holding the position that by *brisement forcé* with a wrench or clubfoot stretcher he could bring the most refractory foot into normal position.

Dr. W. E. WIRT, of Cleveland, believed in resection of some

of the bones after the method of Phelps in cases where tenotomy and linear osteotomy had proved unavailable.

Dr. JOHN B. HAMILTON, of Chicago, agreed with Dr. Marsee in recommending the use of a clubfoot stretcher or wrench. He would not hesitate to apply a force sufficient to comminute the dislocated astragalus if it was necessary to put the foot in position. He had seen no bad results following osteoclasis. The difference between osteoclasis and osteotomy or tarsectomy was precisely that between a simple and an open fracture. In regard to abrasions of the skin, he had not met with any, and decidedly preferred osteoclasis.

New Devices for cutting Bone.—Dr. ALLAN DE VILBISS, of Toledo, exhibited a surgical motor with various forms of saws and drills. He had used the instruments first upon the dead, afterward upon the living. These instruments were adapted for operations upon the skull, maxillary bone, ribs, nasal bones, etc.

The Treatment of Old Cases of Hip Disease.—Dr. WILLIAM E. WIRT, of Cleveland, read a paper in which he said there was no doubt that if convalescent cases of hip disease were carefully and persistently treated during a long period of complete recovery, whatever deformity had existed before and that which accompanied this period could be entirely overcome without operation. When should a case of hip disease be considered to have progressed far enough to permit of the removal of the extension splint and the substitution of a convalescent brace? The solution of this problem was a matter of judgment. It was better to allow the extension splint to be worn unnecessarily long than for the substitution to be made too soon. The deformities requiring correction were flexion and adduction. Dr. Wirt had been surprised in several instances of old cases of hip disease with considerable deformity to find that after the application of continuous extension in bed for a few weeks the deformity was considerably reduced. After a trial of extension in bed with a failure to reduce deformity there remained as a means of correction: 1. *Brisement forcé*, with or without myotomy, tenotomy, fasciotomy, etc. 2. Osteoclasis. 3. Osteotomy. Osteoclasis and osteotomy were to be reserved for cases in which there existed bony union or a fibrous ankylosis of a very firm character. The author reported sixteen cases following Grant's operation.

A Case of Senile Gangrene treated by Amputation.—This paper was contributed by Dr. G. W. H. KEMPER, of Muncie, Ind. The patient was a farmer, aged seventy-three years. After detailing the particulars of the case the author drew the following deductions: 1. While the gangrene is confined to one or two toes, it is best to defer amputation. If the disease extends to the dorsum of the foot, amputation is proper. 2. Amputation below the knee is rarely successful, owing to lack of proper blood supply and the tendency to recurrence of gangrene in the stump. 3. Amputation through the thigh will save a large per cent. of the patients, especially if they are free from general disease. Mansell-Moullin had observed that usually the thigh was small and wasted in the lower third, the artery was sound in Hunter's canal, the flaps were well supplied with blood, and old people, as a rule, resented operations very slightly. Their tissues were not prone to inflammation. 4. When amputation has been performed below the knee, and gangrene appears in the stump, unless the patient is exhausted, it will be proper to perform a secondary amputation above the knee.

A New Method of Operating at the Ankle Joint for Injuries of the Foot.—Dr. I. N. QUIMBY, of Jersey City, read a paper thus entitled. The method consisted in making a curvilinear incision across the dorsum of the foot, beginning anterior to and a little below the internal malleolus and terminating at

a corresponding point a little below the external malleolus, and then uniting the two extremities of the dorsal section by an incision across the sole of the foot, forming an anterior and posterior flap, as in the operation performed by Pirogoff. After forming a short anterior flap and turning it back, he then dissected out the astragalus from its attachments, being careful to keep close to the bone; then, forming a linear posterior flap from the sole of the foot, he made a careful dissection, exposing the anterior half of the calcaneum. This being done, and the soft parts being well retracted by an assistant, the saw was applied so as to remove nearly the anterior half of the bone by an incision from above downward and from behind forward. The sharp edges of the remaining portion of the bone were then rounded off and the sawed surface was applied directly to the articular surface of the tibia between the malleoli, without removing any part of the cartilaginous surface. After stitching up the flap in the usual way a strip of adhesive plaster three or four inches in width was applied from the upper portion of the gastrocnemius muscle to a corresponding point on the anterior surface of the leg, passing directly over the os calcis so as to keep it closely and firmly in apposition to the articular surface of the tibia, and it was kept there until the union of bones had taken place.

The Bacteria of the Surface.—Dr. FRANK J. THORNBURY, of Buffalo, read a paper with this title in which the latest researches were set forth, rational mechanical means of disinfection were summarized, and the non-utility of antiseptics was proclaimed. The varieties of organisms which the cutaneous and mucous surfaces presented in great abundance comprised molds, yeast fungi, bacilli, cocci, and color-producing and odor-producing bacteria. The hairy regions, such as the axillary space, and the interdigital folds were the places of predilection for the bacteria upon the cutis. Myriads of microbes were present in the oral cavity, in the intestinal tract, in the genital tract of the female, in the male urethra, in the conjunctival secretion, and in the cerumen of the ear. Among the masses were germs which were pathogenic, such as the *Fehleisen streptococcus* of erysipelas. The cleansing of the surface constituted one of the most important requirements of asepsis. This pertained especially to the physician's own hands. The disinfection could not be accomplished by the use of antiseptics (so called) which did not even reach the bacteria imbedded in the substrata of fat and dirt. The disinfection must be mechanical, dissolving away the glandular secretions, dead epidermal cells, and vegetable and albuminous substances. For the latter purpose soap, hot water, and brush were used, aided with alcohol and ether, and rubbing with sterile towels. Baths were an important adjunct to asepsis, and one or a number should be administered previous to an operation.

The Etiology, Diagnosis, and Treatment of Ulceration of the Rectum.—Dr. JOSEPH M. MATHEWS, of Louisville, dealt with this subject in a general way. As a matter of convenience, he classified these ulcers under four heads—benign, malignant, tubercular, and syphilitic. He said to this division there might be a valid objection based upon correct pathological grounds. For instance, in this classification he made the term malignant mean cancer, and yet the tubercular ulcer might in truth be malignant without assuming the characteristics of cancer. Again, some writers would have us believe that a tubercular patient was closely akin, at least, to a syphilitic one, or *vice versa*. Benign ulceration was not so frequently found in the rectum as was supposed. Whenever the author met with a well-defined ulceration existing in the rectum, he immediately suspected some special diathesis. It was only when the facility of defecation was interfered with that any danger was to be feared. The lumen of this portion of the gut

was not narrowed by any ordinary causes. For these and other reasons the author had long since been forced to believe that such ascribed causes as pregnancy, dysentery, etc., were not great factors in producing ulceration of the rectum. He then dwelt upon malignant ulceration of the rectum, saying that the rectum was a favorite seat for cancer. Many times the disease was overlooked entirely or diagnosed as some other affection. It had occurred to him several times to have patients referred to him for some trivial rectal trouble and to find cancer instead. The more he practiced the more he was convinced that syphilis was responsible for fully one half of the cases of severe ulceration of the rectum.

The treatment must in every individual case depend upon the known character of it. We could not treat a benign ulcer as we would a malignant one, or a tubercular ulcer as we would a specific one, or the last-named as we would the first-named. Benign growths of the rectum required local applications; malignant, extirpation; tuberculous, the curette; syphilitic, anti-syphilitic and local medication, extirpation, or colotomy.

Inguinal Colotomy.—Dr. LEON STRAUS, of St. Louis, read a paper with this title, in which he entered a plea for more frequent and earlier colotomy in painful malignant diseases of the rectum. He stated his reasons for doing colotomy as follows: 1. It was the greatest modern surgical measure, inasmuch as it completely did away with the function of the rectum, thereby relieving the intense pain caused by defecation. Pain was an inevitable result in advanced malignant disease of the rectum. There were a few exceptional cases, which only proved the rule. 2. The lease of life was extended. There were many instances where it had been considerably extended. Such great authorities as Cripps, Allingham, and Eiselsberg professed to have extended the lease for weeks or months. Were not these most cogent reasons for doing colotomy? 3. The risk of the operation had been minimized. Allingham had done sixty-eight colotomies with only two deaths, and those in total-obstruction cases; Cripps, forty-five, with one death in a total-obstruction case; Edwards, sixteen, with one death, that of a patient who was very septic at the time of the operation; Reeves, sixty-five operations, without a death; and Goodsell, twenty-two, without a death. Statistics showed a death-rate of less than two per cent. By early colotomy, the author believed, the death-rate might be reduced to less than one per cent.

Kraske's Operation, with Report of Cases.—Dr. H. O. WALKER, of Detroit, in a paper with this title, said that when the malignant growth was high up, say two or three inches above the anus, the best operation to do would be Kraske's, that of making an incision down through the second sacral vertebra to the anus to the left of the coccyx and rapidly stripping off the muscular and ligamentous attachments to the coccyx and cutting them away with the bone forceps, together with as much of the sacrum as was necessary to expose the growth. Then we had a full view for enucleating the growth and excising it. It was well known that it was a difficult matter to approximate the ends by the suture method, and the idea had been forced upon the author from his knowledge of the Murphy button that with a large button, say two inches in diameter, which he now exhibited, he could approximate the cut ends of the rectum and by this means prevent the infiltration of fecal matter, which by the other method was an impossibility. In this connection he said he had made the first end-to-end approximation by the Murphy button in a case of fecal fistula on the 8th of December, and the patient on whom he had operated had made a good recovery and within two weeks had been as well as ever, with no evidence of any contraction of the intestine.

Some Heresies regarding Prostatic Pathology.—This paper was contributed by Dr. G. FRANK LYDSTON, of Chicago. The author said that among the many ills which were marked *noli me tangere* until within recent years, and which modern surgery had done much to relieve, prostatic hypertrophy occupied a very prominent position. The surgical resources at present at our command were then briefly stated. The author was daily becoming more firmly convinced that the ideal operation was a combined suprapubic and perineal section performed at an early period. He believed that in many cases this early operation would not only forestall circumscribed prostatic obstructions, median or lateral, but prove directly curative by restoring the normal function of micturition. Suprapubic cystotomy was undoubtedly the best method of draining the bladder, so far as a single operation was concerned, and in many instances it was all-sufficient. When combined, however, with perineal section, prostatic dilatation, and prolonged drainage by a large tube, it often did away with certain conditions which existed in the way of contracted lumen of the prostatic urethra and over-excitability of this portion of the urinary tract, which suprapubic cystotomy alone might not accomplish.

The author believed that the main causes of prostatic disease were at work in many cases, if not the majority, before middle life.

Officers for the Ensuing Year were elected as follows: President, Dr. X. C. Scott, of Cleveland; vice-presidents, Dr. Leon Straus, of St. Louis, and Dr. G. Frank Lydston, of Chicago; secretary, Dr. Frederick C. Woodburn, of Indianapolis; treasurer, Dr. George J. Cook, of Indianapolis. Hot Springs, Ark., was selected as the next place of meeting.

New Inventions, etc.

A VAGINAL SPECULUM FOR USE IN IRRIGATING AND WASHING OUT THE UTERUS AND VAGINA.

BY JAMES C. DAVIS, M. D.,
ROCHESTER, N. Y.

It is very difficult, if not impossible, with the means at our disposal, to wash out the vagina or uterus while the patient is in the recumbent posture without wetting the clothes she wears, as well as the bed or couch on which she lies.

Messrs. George Tiemann & Co., of New York city, have made, at my suggestion, a new vaginal speculum which obviates that difficulty and dispenses with the oilcloth and basin, now in use, placed under the hips of the patient.

Nine months ago I made my first model, and after a score or more of thorough tests I present it to the medical profession for their kind consideration.

The instrument is strong, light, and well proportioned, easy to take apart for cleansing, or to change into other forms, viz.: By loosening the set screw E the upper blade can readily be removed; then loosen the set screw J and remove and reverse the support of the blade and we have the Sims. By leaving the upper blade off with its support we have the Simon's perineal retractor with the addition of a hollow handle to carry *débris*, blood, and mucus through the hose into the waste pail below.

All gynecologists appreciate the necessity of cleansing the surface of the os uteri and vagina of any discharge that may have accumulated, thereby enabling them to detect any trace of granulations or small ulcers present that would otherwise be overlooked.

Before introducing any speculum for diagnostic purposes the os uteri should always be located, then the anointed speculum held in the right hand, between the first finger and the thumb, obliquely to the orifice; the blades, being gently pressed against the perineum, should be rotated upward and backward on its axis, the posterior blade resting on the perineum with the points of the blades in the posterior *cul-de-sac* of the vagina. When the speculum is placed (it being self-retaining), press the

small lever with the thumb of the right hand and set the screw with the left; the cervix uteri being brought well in view between the blades, irrigate with some antiseptic solution and we have a clean surface to treat.

Having experienced comfort and a saving of both time and temper by the use of the speculum described, I have no hesitation in recommending its use as a vast improvement on any form of vaginal speculum known to me.

138 EAST MAIN STREET.

Miscellany.

The New York Academy of Medicine.—The special order for the last general meeting, on Thursday evening, the 2d inst., was a paper on The Importance of Early Attention to the Disability caused by Infantile Paralysis, by Dr. A. B. Judson.

At the next meeting of the Section in Pædiatrics, on Thursday evening, the 9th inst., the subject of intestinal obstruction in early life will be discussed. A case simulating that condition will be reported by Dr. Henry D. Chapin; Dr. John Dornning will read a paper entitled Forms of Intestinal Obstruction, with their Diagnosis; and the discussion on the medical treatment will be opened by Dr. Joseph E. Winters, and that on the surgical treatment by Dr. B. Farquhar Curtis.

At the next meeting of the Section in Genito-urinary Surgery, on Tuesday evening, the 14th inst., Dr. W. K. Otis will read a paper on Aero-urethroscopy, and show a new instrument.

Original Communications.

DRAINAGE OF OVARIAN CYSTS

WHERE THE ADHESIONS ARE SUCH THAT
IT IS IMPOSSIBLE TO REMOVE THE SAC BY CELIOTOMY.*

By A. VANDERVEER, M.D.,
ALBANY, N. Y.

In the diagnosis and treatment of ovarian cysts it is, I think, admitted by all that little more can be said in that direction than has already been accomplished. Without fear of contradiction it may be asserted that each operator has his particular technique that he follows with conscientious care; there may be some slight deviation in the method of emptying the sac, in applying the ligatures, or the use of the cautery to the pedicle, and in closing the abdominal incision. This paper is not intended to touch upon such points, but now and then we meet with a case presenting such strong adhesions of the sac to the various organs that the question is at times forcibly impressed upon us, How far shall we go in making a prolonged operation without immediately resulting in such marked shock as to complicate seriously the patient's living many hours, or a death resulting, the latter being always detrimental to our would-be successful operations in that particular neighborhood where the patient resides? The pathological conditions and changes—the symptoms that are associated with the formation of adhesions—in the developing of a case of ovarian cyst are, I am quite certain, at times passed over too lightly; that is, the patient not infrequently does not lay sufficient stress upon the history of her case when detailing it to the family physician, or to the surgeon who is about to operate.

Localized pains are not sufficiently emphasized, slight accidents are forgotten, and adhesions have resulted very often out of proportion to what seemed trivial causes and conditions.

Again, on the other hand, patients are not infrequently subjected to too many examinations, this being, quite often, the fault of themselves or their friends. They are desirous of seeing too many physicians, and an undue and severe handling of the case may bring about localized pain or peritonitis, resulting seriously when the time comes for operation. There is often an additional and unnecessary nerve strain given to many patients by too frequent and too severe methods employed in the examination of cases of suspected abdominal tumors. Members of our profession have learned fully the danger that results from the use of the aspirator and trocar, and in that direction patients have been relieved from the employment of measures that afterward so frequently produce adhesions externally, as well as suppuration within the sac.

Then, again, cases may be examined with ever so much care; we learn all that is possible of the previous history, as to traumatism that may have occurred, with or without

marked evidence of local pain and peritonitis having supervened, and yet serious adhesions may be present. Some women will tolerate much more readily than others the pains that result in peritoneal adhesions. We know that no two cases go on precisely alike. The rapidity with which adhesions will sometimes form in one case and the extent of their development are out of proportion to some other cases where the ætiological factors have been equally as great. Very properly an operator of experience at the present time does not subject his patient to too long and too nerve-depressing examinations. I take it the experienced operator of to-day has not by any means given up the term exploratory incision in such cases as present with an indefinite history, yet adhesions suspected, though the incomplete operation grows less and less as the number of his cases increases and he becomes more familiar with the operative procedure pertaining to the removal of tumors with many complications. To reach our subject a little more closely, we have made our diagnosis in many cases, and are satisfied that adhesions are present, probably of that variety too strong to yield to the pressure of the sponge or careful use of the hand, that many ligatures will be required, and that possibly adjacent organs may be implicated to the extent that will make the operation exceedingly tedious and dangerous. An exploratory incision is decided upon and which not infrequently confirms our suspicions as to the grade and extent of these adhesions; the patient somewhat, and the friends in particular, are prepared for a severe and tedious operation, the judgment of the operator alone being relied upon to bring the case through successfully. I have not infrequently asked myself the question, when having to deal with such cases, and the patient has been subjected to an operation of an hour, an hour and a half, or two hours, nearly dying, or perhaps doing so within twenty-four or thirty-six hours, from the shock resulting from so prolonged an operation, Would it not have been better to shorten the time in some way, leaving portions of the sac, or the cavity formed from the adhesions to be drained, and thus not carrying our patient too near the condition of exhaustion that results in immediate death? Will not drainage save more patients and bring our cases into a far more comfortable atmosphere of treatment, a larger percentage to go on to permanent recovery, although somewhat tedious, yet not producing that shock and depression upon the friends and neighbors as does death upon the table or a few hours afterward?

Take the following case as one for illustration, although not an ovarian cyst, yet having the form of adhesions to large intestines that I wish more particularly to emphasize in this paper:

CASE I.—Miss McD., aged forty years, unmarried, housewife by occupation, entered St. Peter's Hospital, May 11, 1887, giving the following history: I had had her under observation for nearly ten years, during which time she had enjoyed very good health, with the exception of an enlargement of the lower portion of the abdomen, on the left side. When first noticed it was about the size of a small lemon. This increased very gradually without giving her very much pain at any time. Up to two years ago she had suffered no serious inconvenience,

* Read before the Section in Gynecology and Abdominal Surgery of the First Pan-American Medical Congress.

and at that time I urged her to have an operation. The clinical history, direct physical examination, symptoms, all indicated it to be a case of subperitoneal fibroid, with probable attachment to the left side of the uterus. She had, however, always objected to an operation. During the past two years she has suffered very much more pain and the tumor has increased somewhat rapidly, now, at the present time, filling the entire abdomen, pressing up against the diaphragm, pushing the intestines and contents of the abdominal cavity back into the lumbar regions and behind the liver and above the spleen. One year ago she was quite ill with an attack of localized peritonitis. She is now desirous of having an operation, knowing that the obstruction to the bowels, the pressure upon her stomach, depriving her of food—all of her discomforts convincing her and her friends that in her present condition she can not survive long.

Operation, May 12, 1887.—The tumor was exposed and a distinct pedicle found connected with the left cornu of the uterus, capable of being ligated, but extensive adhesions were discovered connected with the omentum, firmly attached to the ascending transverse and a portion of the descending colon. The tumor was found undergoing cystic degeneration; the loosening of the adhesions became very tedious; it took a long time to free them from their attachment to the tumor, and, in fact, in some places the walls of the tumor were dissected off, hæmorrhage controlled, and the surfaces of the portion of the sac brought together, leaving a mesenteric attachment with the intestine. Glass drainage-tube with gauze packing employed. No hæmorrhage indicated, and but a moderate amount of serum drained.

Operation occupied an hour and a half. Patient recovered fairly well from the effects of the anæsthetic—ether being given—became thoroughly conscious, but died from absolute exhaustion at the end of thirty-six hours.

In the light of experience gathered from other cases since, I realize I could have shortened this operation, bringing a portion of the cyst wall, with the adhesions, into the wound, stitching them there and draining. I know of no other abdominal work that presents with it so great anxiety as the loosening and breaking up of these strong adhesions, particularly when any portion of the intestinal tract is implicated.

Resecting portions of the small intestines becomes possible, yet great care must be exercised here in seeing that the mesenteric attachments are preserved. But when large intestines are involved, resection or anastomosis becomes very much more serious. Adhesions to the solid structures situated in the abdominal cavity give us sufficient anxiety without doubt, but can be managed much more successfully than when we encroach upon the caliber of any portion of the intestines.

It is fortunate for the operator that these cases are not many in number, it is fortunate for us that they are growing less, yet now and then, as I have stated, for some unexplained reason, adhesions form very quickly—much more so in some cases than in others. Some patients have a pain, not particularly distressing to them, not putting them to bed altogether, but it is the pain, nevertheless, of adhesive peritonitis, and we find cases where the clinical history is out of all proportion to the serious adhesions that present. Neglected cases of ovarian cyst will yet present occasionally, and the question seems so pertinent to

us as operators, How far shall we prolong the operation—to what length shall we carry it? Must we not exercise the greatest care in taking into consideration the strength of our patient, and is it not better to cut short an operation and, if possible, drain a portion of the cyst wall, with adhesions, than to pass too many anxious hours in carrying our patient out from the condition of exhaustion, or, sadder still to friends of the patient and interest of operative surgery, witness a death from our overwork in attempting what is really too much for her to bear?

Although this procedure of drainage is a somewhat tedious one, yet I feel I must emphasize that it carries our patient out from the domain of immediate death, and thus does not bring to the friends and relatives that depressed condition of the mind, that aversion they ever afterward have to any form of surgical interference.

Dr. John Homans, as well as many other able operators, has given us a record of cases in which it was found necessary to stitch the sac (owing to the severe adhesions) into the abdominal wound and drain. Can we, however, say, or admit, that our text books have placed sufficient importance upon this line of procedure?

I can not just now give the relative percentage between my cases of drainage and completed operations (but will be able to do so very soon in another paper), yet, to illustrate somewhat more fully my present subject, I desire to speak of the following cases somewhat briefly:

CASE II.—Mrs. O. F., aged forty years, married, housewife by occupation, mother of two children. Presented a very good record of health. Entered the Albany Hospital October 6, 1887, having been seen only recently by Dr. Robert Selden, of Catskill, New York, and who advised an immediate operation.

Records of the hospital state that four years previous she first noticed a tumor located on the left side and supposed to be about the size of a child's head. It grew slowly until June, 1887, and has since then increased very rapidly. Patient has lost much in flesh and strength, bladder irritable, abdomen much distended, tumor fluctuating, and a hard body is felt over the surface of the vaginal vault. Patient has never been tapped. Has received several traumatisms and suffered much from localized peritonitis. An abdominal incision was made and thirteen pints of very offensive liquid pus were removed. The cyst wall was so adherent to the viscera that removal of the sac became impossible, and it was found necessary to stitch the opening in the sac into the abdominal wound by continuous suturing; yet even in doing this it was impossible to hold the sac; it was so friable and rotten that at the point of union, where the drainage-tube was introduced, the cyst wall was lost sight of. Drainage was attempted, but was not so thoroughly successful as could be wished. Owing to some family distress, she was obliged to return home the next day. The wound soon closed after that, and on November 9th her physician, realizing that the sac was filling, aspirated, removing a pint of liquid pus. Between that time and January 23, 1888, she was tapped twice, twenty pints of pus being removed in all. She was now urged to have permanent drainage established and the remaining portion of the cyst washed out, but she was so unfortunately situated that it was impossible to carry out the suggestion. She was aspirated again, but ultimately died from an attack of pneumonia.

This patient, could she have had proper nursing and thorough drainage kept up, I have no doubt would have

made a permanent recovery. I feel quite certain that, had we persevered in attempting to remove the adherent cyst, she would have died early from shock.

CASE III.—Mrs. C. H., aged fifty-five years, married, native of Germany, housewife; residence, Adams, Mass. The patient well as a girl; first menstruated at nineteen; always healthy; has had ten children. Present trouble began seven years ago; at that time the menopause occurred. About three years ago she began to increase, most noticeably about the waist; last summer she experienced pain in the abdomen for the first time. Appetite good, bowels regular. Admitted to the Albany Hospital on December 8, 1889. After careful examination, diagnosis made of ovarian cyst, with probable adhesions due to the local peritonitis she had evidently had. Operation was decided upon and incision made on December 9th in the usual manner; but the cyst was found thoroughly adherent to the parietal peritoneum and to the omentum and large intestines to that extent that it was impossible to remove it. The cyst was stitched into the abdominal wall by continuous sutures, patient making a good recovery. After continuous drainage for about ten weeks the sinus remained permanently closed, and she recovered her health sufficiently to return to her household duties. This patient remained well up to January, 1893, when she again began to enlarge, and now presents with a cyst about half the size of the former one. I am of the impression that the other ovary has taken on a development of cystic tumor, and that we have here an embarrassing situation as to whether it will be possible to remove it, even if it possesses no adhesions of its own.

CASE IV presents a condition bearing more particularly upon this paper—that of Mrs. J. McD., married, mother of several children, a patient of Dr. H. E. Mereness, of Albany, and who gave a history of an abdominal tumor of more than three years' growth. She was a very fleshy woman, and it was exceedingly difficult to make out the diagnosis, yet from the history it was believed she was suffering from either a fibrocystic or a multilocular ovarian tumor. Owing to pressure against the diaphragm, from obstruction of the bowels, and edema of the lower extremities, it was decided to operate. On January 10, 1892, the operation was done. We found a thick cyst wall with three large cavities, containing a brownish-looking fluid, thick in character, like that which we not infrequently get from multilocular ovarian cysts, and, on breaking down the partitions, I was able to evacuate the contents, so as to bring the abdomen down to about its normal size; but I found the most extensive and serious adhesions possible. The large intestines were severely implicated, as were also portions of the abdominal parietes, and, when drawn upon, dented the external appearance of the abdominal wall. With my hand I cleaned out the contents of the cysts as thoroughly as possible, breaking down partitions; brought the edges of the cyst wall up into the abdominal wound, stitched with continuous suture, placed in two glass drainage-tubes, washed out thoroughly with a solution of mercuric bichloride at times, occasionally using carbolic acid, but mostly a solution of boric acid, continued drainage, and in good season had the satisfaction of seeing this patient make a complete recovery, although she was under the careful treatment of Dr. Mereness and myself for a period of between three or four months. She is now well and in every way able to attend to her household duties.

I am certain that, had we gone on and prolonged the operation, this patient would have been placed in serious jeopardy as to her recovery, and I feel that it would really have been impossible to have detached the adhesions.

CASE V.—Mrs. N. O., aged sixty-two years, housewife by

occupation, under the care of Dr. Barry, of Schenectady. Admitted to Albany Hospital on November 11, 1892; married; mother of four children; menopause at fifty; no unusual personal or family history. She says she did not notice any enlargement of the abdomen until a year ago, when she began to increase quite rapidly. Has not suffered any particular pain; appetite very good; some bladder irritation, but the bowels have behaved well. For the past two or three years she has frequently been joked by her friends as to her growing fleshy. Examination of the urine shows the kidneys to be in a healthy condition. No swelling or edema of lower extremities. Pulse about 80, but slight rise in temperature. Operation on November 12, 1892, believing the case to be one of multilocular ovarian cyst. On entering the sac I drew off nearly three quarts of purulent-looking fluid. There were no pelvic adhesions, and I had no difficulty in reaching a fairly good pedicle associated with the left ovary; but, on passing my hand up along the cyst wall on each side and attempting to reach to the superior surfaces of the cyst, I found the adhesions so serious and so firmly attached to the transverse colon as to make it soon evident it would be impossible to loosen them with any degree of safety. I therefore emptied the cyst walls thoroughly well (it really being a multilocular ovarian cyst), closed the openings in the sac, reached the pedicle, ligated it in two places, made a section between the double ligatures, drew the lower portion of the cyst wall well up into the incision, stitched carefully to the abdominal wound, reopened what was left of the cyst, cleaned out thoroughly, placed a glass drainage-tube down in the cavity of the pelvis (it drained quite successfully for three or four days and was then removed); also placed two glass drainage-tubes, packing well around them with iodoform gauze, in the remaining portion of the cyst wall, and then continued thorough drainage afterward. This patient made a good recovery, and is now able to get out and about, enjoying life with much comfort—a great joy to her anxious children.

CASE VI.—Mrs. C. M., aged thirty-seven years, married housewife by occupation, came under my observation on April, 20, 1893, with the following history: Sister died of phthisis at about the age of thirty; otherwise family history good. Patient never strong; has had six children; no miscarriages; always regular in menstruating. Seventeen months ago she had pleurisy, with effusion of left side; was aspirated by Dr. Macdonald, of Schenectady, and, as she said, a large amount of fluid removed. From this she made a good recovery; but about this time she noticed an enlargement of the abdomen. In February, 1893, the abdomen was aspirated and about three quarts of fluid removed. Examination reveals a well-defined tumor in the right side of the abdomen, filling the pelvis and extending up above the umbilicus; fluctuates somewhat distinctly, but gives a sensation of being held firmly in position. Diagnosis was made of tubercular peritonitis, with fluid, probably held in pockets by adhesions, between folds of intestines. Since her last aspiration she has gradually filled, and has lost in strength until now her general health is somewhat seriously affected. Exploratory incision advised, to be followed by permanent drainage. Section made on May 3, 1893. Quite an amount of ascitic fluid was removed, and then an ovarian cyst connected with the right ovary, holding nearly a quart of fluid, was discovered. Here the adhesions to the cæcum and the sheath of the iliac vessels on the right side were so firm with adhesions to the transverse colon and stomach, which were brought down below the umbilicus, that I could do but one thing, and that was to bring the cyst walls up into the incision, stitch, and drain. Drainage was carried out successfully, and the patient has made a good recovery.

CASE VII.—Mrs. L. Y., aged fifty years, housewife, referred

to me by Dr. Moon, of East Springfield, N. Y. Family history exceedingly good; thorough absence of any malignancy or tubercular disease; both father and mother still living and in fairly good health. First menstruated at eleven and has always been regular. Married at the age of twenty-four; never pregnant. Ceased to menstruate at the age of forty. When eighteen years of age was thrown from a horse and thinks she was never quite as well afterward. Had scarlet fever when twenty-three years of age. Fifteen years ago she suffered from some pelvic distress and consulted Dr. Thomas A. Emmet, of New York city, who gave her the diagnosis of fibroid tumor of the uterus, and advised her to let it alone. Eight years ago was thrown from a wagon, striking upon her buttocks and receiving a severe jar. Was weak for a long time afterward, feeling much soreness in what she supposed to be the fibroid; however, she remained in very good health up to December, 1892, when she noticed an enlargement of the abdomen low down and on the left side. March, 1893, this had increased very decidedly. About the 1st of June she had very severe attacks of pain for three days and nights, suffering a great deal, and has since had several such attacks, but thinks they have gradually decreased in severity. She says the growth has enlarged very slowly since she first discovered it. Has suffered much inconvenience from constipation, more especially since noticing this last enlargement. I saw her August 1, 1893; was able to locate a fibroid tumor on the right side of the pelvis low down and about the size of a goose egg; the uterus was drawn up to the left, the broad ligament on that side seemed contracted, and the uterus fixed at that point. Above the symphysis and extending close up to the xyphoid cartilage, filling the lumbar regions thoroughly, could be made out a fluctuating tumor, evidently ovarian in character. I advised an immediate operation in view of her general emaciation, her inability to take much food, pressure upon the kidneys and other important organs being such as to give her great inconvenience and distress. She had remembered thoroughly well Dr. Emmet's advice and was reluctant to have any operative interference, but when the case was fully explained she seemed more willing. She was detained in various ways and did not enter the Albany Hospital until August 29, 1893. After proper preparation, operation was performed the next day, the 30th. I had anticipated meeting with adhesions, her history being in that direction. Had no trouble in exposing the sac and emptying its contents—a brownish looking fluid—but found, as I withdrew about two thirds of the sac, that it was firmly adherent to the rectum, including the sigmoid flexure, dipping down into the pelvis on the left side, and also adherent to the subperitoneal fibroid, which had its relation in connection with the right cornu of the uterus. After thorough examination I found that it would be more than dangerous to attempt to dissect the sac, which was held so firmly by strong adhesions. I therefore stitched the deeper portions of the sac to the abdominal incision, removed that portion which was free, emptied the remaining part thoroughly, being in size not more than would hold a pint, placed in gauze drainage, also a glass drainage-tube to the deepest portion—operation not being a prolonged one. Patient has gone on uninterruptedly with a train of satisfactory symptoms, doing as well as could be desired.

I am fully aware that every operator must, at the time of operating, be the judge as to how far he may go in the removal of tumors associated with strong adhesions. In view of the very excellent system of drainage that can now be employed, in view of the impression that prevails among the friends of the patients that they ought not to die upon the table or from the immediate effect of shock except in

very rare instances, I am prone to believe that we should be somewhat conservative in our course in these cases; yet I am frank to admit that it is much more pleasing to the operator, much more a test of surgical skill, perhaps, to remove all that which he has attacked as a pathological condition, and bring his patient into as normal a state as possible. In carrying out drainage in these cases the patient should be put in the care only of a conscientious, judicious nurse. A glass drainage-tube should be employed and made to reach to the deepest portion of the cyst or whatever remains of the cyst walls and adhesions. A rubber drainage-tube can not be relied upon at first. Gauze packing is much preferable to the latter. We are bound to respect pelvic adhesions when they implicate the sheath of important vessels resting there, and gauze drainage is the safest. Deep-seated pelvic hæmorrhage is not always so easily controlled, and has troubled more than one operator when he has encountered it. No one will deny but that abdominal incisions can certainly be treated with a greater degree of comfort than where the large intestines are implicated.

We have seen much in days gone by as to the use of the thermo-cautery and preparations of iron in controlling hæmorrhage resulting from the breaking up of adhesions, and yet I should like to get the honest expression from the operators of to-day as to how often these two agents are made use of. Ligatures and drainage-tube, in one form or another, beyond a doubt are the best agents we have for controlling hæmorrhage in these cases where we are obliged to separate extensive adhesions. I am not unmindful of sapræmia and septic conditions in cases of incomplete removal of the sac, and I do not want to convey the impression that I would in the least surrender any case that it is possible to make a complete operation in. I am fully aware that drainage carries with it some uncertainty, especially in the effort to get consolidation by collapse of the walls of the sac and where the detritus is to be removed in larger portions from time to time. I would advocate this line of treatment only in such desperate cases as where we feel our patient is likely to be carried beyond the point of possible recovery, and to die in shock because of the too severe tax made upon the weakened vitality of the system. These cases of drainage require the utmost care and watching as to general treatment, diet, sanitary surroundings—all becomes of the greatest importance where the necessity of drainage is the only method of procedure.

28 EAGLE STREET.

PHARYNGEAL VOICE:

ILLUSTRATED BY PRESENTATION OF
A PATIENT WHO PHONATES WITHOUT A LARYNX
AND WITHOUT THE USE OF HIS LUNGS.*

By J. SOLIS-COHEN, M. D.,

PHILADELPHIA.

We are all aware that every now and then Nature has ways of restoring a function that has been destroyed by

* Read before the American Laryngological Association at its fifteenth annual congress.

disease or surgical procedure in a manner which is very surprising and unexpected. I show you a very remarkable instance of that in this patient, from whom, fourteen months ago, I removed the larynx (leaving the epiglottis) and the first ring of the trachea for a cylindrical epithelioma. The case was reported to this association last year, shortly after the operation. In order to prevent as much as possible a septic pneumonia, I stitched the trachea to the skin by several sutures of silk, and since then there has been no communication whatever between the trachea and the mouth. Some months after the operation I found that the man was able to make a clucking sound. I encouraged him in this as a factor in making himself understood, and he has succeeded to a wonderful extent. His larynx should be here; it was sent by express from Philadelphia yesterday and ought to have been delivered this morning, but it has not yet arrived. I will ask this man to speak to you in a few moments, and you will notice then that he swallows the air and a little bag of skin is formed in the neck just above the tracheal orifice, which is utilized as the motive power of phonation. Where his voice comes from I do not know positively. He says it comes from down here, below, just above the bag of air in the neck. In all probability the constrictor muscles of the pharynx are utilized as phonating reeds set in vibration by the air as it escapes from the sac in the neck. I have examined the patient carefully while phonating time and again, and know positively that the new phonating reeds are not the posterior palatine folds, as I thought at first, nor are they the epiglottis and a transverse fold of the posterior wall of the pharynx. Dr. Lefferts, who removed a papilloma from the man's larynx eighteen years ago, says he thinks the man phonates with the tongue and lips; certainly not with the epiglottis. He can produce the sounds while the laryngoscopic mirror is in position, and the voice does not come from the region of the larynx. His voice is modulated much better than it would be by any artificial instrument.

Another curious feature of the case is this: After the operation a slight fistula remained in the track of the wound. In order to close it I inverted the skin and fastened it together, and on those inverted flaps of skin the hairs of the beard have continued to grow. Upon examining the man, you will see that along the line of the cicatrix is a white stripe to which my attention was first called by my assistants, who thought it might denote a recurrence. I am satisfied now that there is no recurrence, but that the epithelial tissue is undergoing some change. This man sleeps without any tube. The manner in which the trachea is united with the skin dispenses with the necessity for a tube. He prefers to wear it during the day, because it gives him some support, and he speaks better with it. It seems to give a fulcrum from which the expulsion of air from the sac is better controlled. After the operation I nourished this man *per rectum*. I stitched the trachea forward as you see, and during the two weeks of treatment kept the bed tilted so that the head was lower than the shoulders, and the fluids, by gravity, went out of the wound instead of down into the lungs. There was no dressing whatever applied to the pharynx; not even a bit of gauze.

Shortly before, I had a case with Dr. Gleitsmann which terminated fatally, in which the patient was very much troubled with efforts to swallow by reason of the packing in his pharynx. In this case I saved the patient from that trouble. The wound was loosely brought together with stitches and allowed to granulate. There has been no pain since the operation.

CREASOTE

IN THE TREATMENT OF PHTHISIS PULMONALIS.

By FREDERIC M. WARNER, M.D.,

VISITING PHYSICIAN TO THE CITY HOSPITAL;
CONSULTING PHYSICIAN TO THE FRENCH HOSPITAL
(DEPARTMENT OF DISEASES OF CHILDREN).

The administration of creasote to patients suffering from pulmonary phthisis is now an established therapeutic measure. The benefit to be derived from the proper employment of this drug is unquestionable. Beverley Robinson, with whose name we instinctively associate this method of treatment, expresses himself in his latest contribution* on the subject thus:

"With an additional and broader field of experience the results obtained have not become more doubtful; on the contrary, they have been confirmed and strengthened."

During a somewhat extensive employment of this remedy in phthisis for the past four years, both in hospital and in private practice, I have watched with great encouragement the steady gain in the results obtained; but it has been only during the latter half of the time that the positive value of creasote as an agent for combating most powerfully the effects of this disease has been made apparent.

Formerly my custom was to administer the drug in small doses, exceptionally giving more than six or eight minims daily. During the last couple of years, however, the doses have been largely increased with correspondingly better results.

An explanation of the favorable action of creasote has as yet not been given. Coret's experiments on guinea-pigs yielded negative results. It seemed to have no influence on the infection of these animals with tubercle bacilli. He ascribed the favorable effects to its action in lessening the bronchial secretion and improving the appetite. Summerbrodt and many other observers, however, believe in the distinctly curative value of the remedy.

It is my rule to administer creasote in the following manner: Beginning with one minim three times daily, I increase one minim each day until the limit of tolerance is established, watching the effect of the drug upon the stomach and bowels and causing a daily examination of the urine to be made.

The cases under observation in which creasote has been employed have, as a result of the treatment, presented certain features common to all and quite characteristic.

The general condition of the patient, as a rule, rapidly improves; in some cases the appetite is better, the cough at first becomes less during the daytime, while remaining

* *Medical Record*, Feb. 27, 1892.

quite as before during the night; after a time, however, it also lessens at night. If the sputum has been tinged with blood, this condition disappears, contrary to what might be expected, as creasote is said to congest the bronchial mucous membrane; and while at first the sputum is not much lessened, if at all, its character is changed; from being thick and yellow—muco-purulent, in fact—it becomes thinner, frothy, and contains less solid matter. In no case where previously attacks of hæmoptysis had occurred have they taken place after the creasote treatment has been established. The night sweats grow less and in many cases entirely disappear, and after a while there is a total absence of the daily fever. The weight of the patient always increases at first, then is apt to remain stationary, and in exceptional cases may lessen, and then a gradual increase takes place. The first increase in weight is no doubt due to the improvement in appetite and in the greater ability of the patient to properly assimilate the food consumed.

In other cases, although at first there may seem to be an improvement in the general symptoms, yet the extent of the lesions preclude any definite or marked bettering of the patient's condition.

In any case I have been much struck by the change in appearance of patients who have been on this treatment for some time. The facial expression is very different, the gain in weight, the absence of hectic, the feeling of improvement in the physical condition, all undoubtedly exert a marked effect psychologically, which is unmistakably stamped upon the patient's face.

Administration.—A certain familiarity with the employment of creasote in the treatment of phthisis pulmonalis has taught me that the indication is to saturate the patient as far as possible. We need to get something more than a tonic effect; we want the specific action of the drug, whether it be upon the micro-organism or upon the poisonous secretion, or whether it acts by rendering the soil unsuitable for the growth and development of the bacilli; or whether the effects are due to an improved nutrition. The great objection urged against the administration of antiseptic substances by the mouth has, been that the drug can not be absorbed in sufficient amount to effect the purpose.

I think, however, that the exhibition of creasote in doses small at first and gradually increased meets the point. I have personally, in several cases, demonstrated the fact that very large amounts of creasote may be retained without discomfort—one patient reaching a daily amount of two hundred and fifteen minims—while many clinicians have given as large or greater amounts.

Without doubt a valuable aid to the internal administration of creasote will be found by the coincident employment of *antiseptic inhalations*.

Harris* has reported one hundred and fifty cases treated by means of "instillations." These consist of a number of volatile antiseptic substances, which are placed on the sponge of a naso-oral inhaler and through which the patient respire. This treatment is instituted several times daily and the results obtained have been most satis-

factory; and this investigator urges careful and prolonged trial of what he calls "the most reasonable method short of inoculation for introducing antiseptic substances into the lungs." He thinks that this method of medication is especially valuable after the disease has advanced beyond the first stage. Iodoform is the drug which he has principally employed.

My custom is to use creasote combined either with terebene or ether in a fifty-per-cent. solution, ten or fifteen minims dropped on the sponge of a Robinson's inhaler, and employed every second or third hour, and in some instances where marked benefit has been derived from the employment of this measure the respirator has been worn almost constantly.

At various times I have tried the effect in a large ward of the City Hospital of allowing an antiseptic mixture to simmer gently over a low fire during the night time. This mixture generally consists of oil of eucalyptus, carbolic acid, and turpentine. A drachm each of the first two and two drachms of the last are put in about a quart of water in a shallow dish and heat applied. The effect is to fill the ward with a pungent aromatic vapor, which has a markedly sedative action, it being noticed by the nurses in attendance that the coughing is not nearly so general or frequent.

Inoculation.—It has been urged by many that the most direct method of dealing with the tubercle bacilli or their virus is by inoculation. I have not been able, however, to employ creasote successfully in this manner, although I have frequently tried subcutaneous injections of the remedy in sterilized oil, with the result of causing so much local disturbance that to continue has been impossible.

Creasote Poisoning.—In regard to the ill effects of the drug I have not much experience; there is no doubt that the maximum dose of creasote varies greatly in different subjects; in my experience, a few patients have not been able to tolerate even the small initial doses, complaining at once of nausea, vomiting, and gastric pain. As a rule, these patients have been hysterical women upon whose statements I could place no definite reliance, but have always discontinued the use of the remedy upon the complaint.

Occasionally during a course of treatment patients will experience attacks of diarrhœa, slight in character, easily controlled by large doses of bismuth and by holding the amount of creasote at the number of minims of the last dose before the attack of sickness, until the symptoms of intestinal disturbance are past, then proceed to increase one minim daily, as before.

In other cases undoubted irritation of the stomach and bowels was produced by the employment of creasote, and in all cases where this occurred, and the symptoms did not abate after twenty-four hours, I commenced to diminish the amount of the drug one minim daily until the point was reached where it could be tolerated.

In some instances I have noticed marked head symptoms—dizziness, pain, and double vision—all of which disappeared under diminished doses.

In no cases have I noticed the slightest change in the

* St. Barth. Hosp. Reports, vols. xxv and xxvi.

urine from patients under treatment with either large or small doses, although daily examinations of the urine are made, but I should hesitate to advocate the employment of creasote in cases of phthisis when there was already existing renal disease.

It is true that many patients can not take large doses; for example, my attention was called recently to a young woman who was taking only six minims three times daily, when she was attacked by nausea, vomiting, and slight diarrhoea, together with headache and vertigo, accompanied by a sense of great weakness, which persisted. There seemed to be an entire absence of hysteria. Diminished doses promptly caused a subsidence of bad symptoms, and after a short period of rest I shall try once more to increase the amount.

Among the many cases which I have had and still have under observation, very few have reached their dose limit.

CASE I.—A. B., female, aged thirty-five, phthisis both apices, second stage, had reached a daily maximum dose of eighty-seven minims, with manifest improvement in all the physical signs—a cessation of night sweats, of hemorrhages, much lessening of the cough and expectoration, a considerable increase in weight—when suddenly she began to experience nausea and vomiting, slight continual headache, vertigo, trembling in the extremities, and slight difficulty in vision. These symptoms continued for several days while the daily dose of creasote was kept the same, without any increase; then, as there was no improvement in the symptoms, it was evident that she had exceeded her limit of dose, and in order to arrive at the amount that she could safely take, the daily dose was diminished one minim. When the number seventy-eight was reached, the toxic symptoms, which had been gradually subsiding, entirely disappeared, and the patient was held at this amount, which was believed to be the maximum daily dose that she could tolerate.

The following case is interesting from the fact that it shows so well the distinct gain while under treatment, the loss while the creasote was stopped, and the improvement after the treatment was begun again:

CASE II.—W. F., male, aged forty-nine years at the time of commencing treatment, March 30, 1892, had a cavity at right apex, with large and fine râles over both lungs.

June 16th.—He felt so much better that he insisted upon going out of the hospital. At this time there was a marked improvement in the physical signs; his weight was exactly what it had been at the beginning of treatment—one hundred and twenty-one pounds; the appetite was good, the cough and expectoration had greatly decreased, and he was getting a daily dose of sixty minims of creasote.

August 8th.—He was readmitted to the hospital.

Physical Examination.—General emaciation, depression marked above both clavicles. Percussion: dull above both clavicles, tympanic below right. Auscultation: bronchial breathing heard over left lung, with many fine and some bubbling râles; expiration prolonged; cavernous breathing over apex of right lung; bronchial with fine râles over base. Posteriorly, bronchial breathing and fine râles over both lungs.

At this time also there had developed a laryngitis, and there was much cough and mucopurulent expectoration and night sweats.

The patient was at once put on the creasote treatment again

with excellent effect: diminution in the cough, night sweats, and amount of expectoration, and an increased weight as follows: August 8th, 115 pounds; August 19th, 118 pounds; August 27th, 118 pounds; September 1st, 117 pounds; September 23d, 123 pounds.

On the date of the last weight the patient was getting forty-one minims of the creasote, and suffered no inconvenience therefrom.

CASE III.—M. G., male, aged thirty-five years; phthisis both apices, second stage. Began creasote treatment April 28, 1892. Patient had been ill about six months, had lost much flesh, profuse night sweats, hectic, and considerable mucopurulent expectoration.

He rapidly improved in every respect under treatment until July 27th, when he complained of nausea and a little diarrhoea; at this time his daily dose of creasote was ninety minims; through an error the medicine was stopped, and my attention was not called to the case until a week or ten days afterward, when, as such a length of time had elapsed, we were obliged to recommence with small doses, increasing two minims daily.

His record of weight is as follows, and shows well the steady improvement up to the time that the creasote was stopped, then the drop during the period of interruption, and the constant improvement afterward: May 31st, weight 131 pounds; June 6th, weight 131½ pounds; June 11th, weight 134 pounds; June 14th, weight 132½ pounds; June 18th, weight 135 pounds; June 22d, weight 134 pounds; June 27th, weight 131 pounds; July 11th, weight 137½ pounds; July 16th, weight 137 pounds; July 19th, weight 137 pounds; July 23d, weight 137 pounds; July 25th, weight 139 pounds; July 27th, creasote stopped; August 8th, resumed, weight 135 pounds; August 15th, weight 138 pounds; August 19th, weight 141 pounds; August 22d, weight 142 pounds; August 27th, weight 140 pounds; September 1st, weight 144 pounds; September 23d, weight 146 pounds; October 10th, weight 146½ pounds.

When this patient left the hospital on October 10th there was a marked improvement in his case. There had been a steady amelioration of all the conditions existing at the time when the treatment was begun; besides the gain in weight of fifteen pounds and a half, the night sweats had disappeared, as well as the hectic; the cough was hardly present, except at night, troubling him but little; slight expectoration, and with good appetite.

Physical Examination.—In front on right side over apex and upper part of upper lobe, bronchial voice; over corresponding area behind, bronchial voice and breathing, no râles.

This patient returned to the hospital on December 6th. Having been half starved and having had no creasote, his weight was 144½ pounds, but there was no appreciable difference in the physical signs. His general condition improved and he left the hospital against advice January 16, 1893. Weight, 146½ pounds, and with the condition of the lungs apparently the same.

Glascow* says that he finds it beneficial to intermit the treatment for a week or ten days when patients have taken large doses for some time. I do not see anything to be gained by it, and Case III shows a distinct loss in weight during the periods of enforced abstinence from the drug, which must necessarily be taken as indicative of impaired nutrition, if not of a retrograde condition in the lung.

* *The Climatologist*, June 15, 1892, p. 295.

CASE IV.—W. K., male, aged thirty-nine years; phthisis second stage. Was put on the treatment February 25, 1892, with the result that the night sweats disappeared, but a slight cough remained, the pain in the chest vanished, the sputum became slight in quantity and thin and frothy. On July 25th examination revealed only an occasional fine subcrepitan râle heard on right side over suprascapular region; the patient declared that he was well and insisted upon leaving the hospital. At this time his daily dose of creasote was ninety minims and the record of weight as follows (the weights previous to May 23d were lost):

May 23d, weight 125 pounds; June 3d, weight 127½ pounds; June 11th, weight 127½ pounds; June 18th, weight 131 pounds; June 27th, weight 131½ pounds; July 11th, weight 131 pounds; July 19th, weight 133 pounds; July 25th, weight 131 pounds.

CASE V.—J. D., male, aged thirty-four years; phthisis, second stage, with much expectoration, continual cough, dyspnoea upon slight exertion, night sweats, loss of appetite and strength. Had been sick about a year, and during past seven months had lost eighteen pounds in weight. On July 28th commenced taking creasote. September 1st the daily dose had reached twenty-five minims, with a diminution in all of the bad symptoms and the following record of weight, which is particularly worthy of note from the fact that before beginning the treatment with creasote the loss in weight had been so steady and marked:

August 15th, weight 146 pounds; August 19th, weight 143 pounds; August 22d, weight 149 pounds; August 27th, weight 149 pounds; September 1st, weight 151 pounds; September 12th, weight 152 pounds.

On this last date, September 12th, with a daily dose of thirty-five minims, the patient felt so well that he left the hospital at his urgent request to be allowed to get to work.

I regret that the copies of the results of the physical examination in this case are lost.

Without going into details of cases, I append a list from my notes at random of patients in the first and second stages of phthisis, with the amount of creasote taken daily and the result with reference to the weight alone.

Name.	Beginn.	Ended.	Weight.	Amount.
G.	May 25.	July 23.	127-130 lbs.	48 minims.
R.	May 22.	June 23.	123-120 "	45 "
H.	June 2.	June 23.	134-131 "	32 "
H.	April 14.	July 15.	155-175 "	103 "
O'B.	May 25.	July 23.	133-133 "	104 "
D.	July 15.	Dec. 16.	118-117½ "	65 "
McK.	May 23.	Jan. 16.	142-145 "	57 "
K.	Sept. 27.	Oct. 7.	110-112 "	11 "
V.	Oct. 4.	Dec. 16.	120-127½ "	45 "
D.	Oct. 14.	Oct. 22.	146-152 "	10 "
P.	Oct. 18.	Dec. 26.	152-152 "	80 "
McG.	Sept. 14.	Jan. 16.	133-132 "	53 "
L.	Nov. 1.	Dec. 26.	125-148 "	60 "
A.	Nov. 3.	Dec. 14.	106½-122½ "	43 "
McF.	Nov. 17.	Jan. 16.	119-120 "	43 "
S.	Dec. 9.	Jan. 16.	146-148 "	27 "
N.	Dec. 28.	Jan. 16.	157½-164 "	8 "

The foregoing are a few of the cases of which the notes are more or less imperfect, and the table merely helps to show that, as a rule, patients in the early stages of phthisis are markedly benefited, at least in weight, by large and increasing doses of creasote; and where the body increases in weight the destructive process in the lungs is at least not extending. It is true, as I have before said, that some pa-

tients reach their maximum dose early; for example, my attention was called recently to a girl who had reached a daily dose of only eighteen minims, when nausea and vomiting, with slight diarrhoea, vertigo, and headache, accompanied by a sense of great prostration and weakness which persisted, warned me that her maximum dose had been exceeded, and she is now being given one minim less daily, with a gradual diminution of the bad symptoms.

In hospital cases a factor which must be taken into consideration while studying these cases is what part in the general improvement in the patient's condition may be referred to the regular hours and better food than most of them are accustomed to at home? The answer to this I think will be found by referring the inquiries to the phthisical patients inhabiting wards in any general hospital where the routine treatment of sedative cough mixture, cod-liver oil, and poor whisky is followed. In how many of these cases is there marked increase in weight and corresponding improvement in the physical signs of the chest?

A question which is frequently asked in reference to this treatment is regarding the presence of the tubercle bacilli in the sputum—whether or not this method diminishes their number. I can only say that in the cases where the sputum was examined the bacilli did not disappear; unfortunately, however, in many of the hospital cases no examinations were made.

In reference to the mode of administration of the drug it has not seemed to make much difference. I generally order it to be taken after meals in milk or sweetened water or wine, or in combination with a bitter, such as cinchona or gentian, or in a little whisky and water.

From the results obtained I have a strong belief in the present and future value of creasote in the treatment of pulmonary phthisis.

66 WEST FIFTY-SIXTH STREET.

SALIVARY CALCULI,

WITH REPORTS OF CASES.*

By CLINTON WAGNER, M. D.

ALTHOUGH cases of salivary calculi are of very infrequent occurrence, still quite a number of cases are on record. The first of which I have found mention dates more than two centuries back. In my practice, extending over a period of more than thirty years, I have had only three cases, and assisted in the operation for the removal of a fourth at a clinic with which I was connected.

These concretions are formed by the deposit of earthy salts (chiefly the phosphate of calcium) from the saliva in the excretory ducts leading from the gland or in the body of the gland itself, in which case the pain is greater and the removal of the calculus more difficult. The cause of the deposit is an obstruction to the flow of saliva either to or through the excretory duct. I do not think that the gouty or rheumatic diathesis is a factor in the development of the concretions.

* Read before the American Laryngological Association at its fifteenth annual congress.

They are most frequently found in the sublingual gland or its excretory duct, the duct of Bartholin, and may be recognized by a tumor under the tongue on one side or the other of the frænum; it is sensitive upon pressure and is sometimes but not always fluctuating. If the body is lodged in Wharton's duct, in addition to the sublingual tumor there will be enlargement of the submaxillary gland; non-enlargement of this gland indicates that the concretion is lodged in the duct of Bartholin. The concretions are sometimes found in Stenson's duct, in which case there will be enlargement of the parotid gland.

The subjective symptoms are pain and difficulty in mastication and deglutition, with more or less impairment of speech. When the parotid and submaxillary glands are inflamed from the presence of these bodies the pain at times is agonizing.

In a case of suspected calculus in a sublingual tumor where there is fluctuation, a free incision should be made in order to give vent to the fluid contents; the calculus, if there is one, will probably be released from the duct and will escape through the opening made by the knife. If the tumor is solid and firm, a small opening should be made for the introduction of a very fine probe, with which an exploratory examination may be made; if a calculus is felt, the incision should be freely enlarged and a small forceps introduced with which it may be seized and removed. I think that many of the so-called cases of ranula are caused by small calculi impacted in the duct of Bartholin. When the calculus is imbedded in the substance of the submaxillary gland its removal is attended with great difficulty.

Dr. J. Mason Warren, of Boston,* attempted the removal of one by external incision and failed; he finally reached it by incision through the mouth and removed it piecemeal with a small polypus forceps, the patient having first been put under the influence of ether.

In the first case of salivary calculus that came under my treatment the patient consulted me about twenty-three years ago, a man aged forty five years. He stated that three years before coming to me a swelling began under his tongue which slowly increased in size. At the time of consulting me it was painful and interfered greatly with speech and mastication. The tumor was fluctuating and on the right side of the frænum. I made a free incision, from which escaped about half an ounce of a viscid, semi-transparent fluid and a calculus. There was no enlargement of the submaxillary gland. The concretion had lodged in the duct of Bartholin. It weighed eight grains and was composed mainly of phosphate of calcium and organic matter. I sent it to the Army Medical Museum at Washington, and it is numbered 5,735, Section 1, in the collection.

CASE II.—Colonel W., aged sixty-five years, a retired officer of the army, stated that for over two years he had experienced pain and discomfort from a swelling under his tongue, with an enlargement externally. An examination disclosed a sublingual swelling to the right of the frænum, and also enlargement of the submaxillary gland of the same side. No fluctuation could be detected in the sublingual tumor; on the contrary, it was firm and quite sensitive upon pressure. Suspecting a calculus in Wharton's duct, I made a small incision, and after a careful exploration with a fine probe I detected a hard body;

and upon enlarging the incision I had no difficulty in seizing and removing a small calculus weighing seven grains. The sublingual swelling disappeared with the removal of the concretion, but the submaxillary enlargement remained. Several weeks later I introduced an exploratory needle into the body of the gland through the mouth, but did not discover another calculus, as I thought might possibly be the case. The swelling of the gland, I learned afterward, disappeared in course of time.

CASE III.—Mrs. B., aged thirty-six years, applied for treatment at the Metropolitan Throat Hospital. She stated that for eighteen months she had been annoyed by a swelling under her tongue which was painful and interfered with mastication. An examination revealed a firm, hard tumor, sensitive upon pressure, and to the right of the frænum; there was no enlargement of the submaxillary gland. An opening was made sufficiently large to admit a small fine probe, and after a few minutes' careful search a hard body was felt. The incision was enlarged and a small calculus removed from the duct of Bartholin weighing four grains.

Some years ago at the London Throat Hospital I had an opportunity of examining and assisting in the operation for the removal of a very large calculus from the duct of Steno. As it is the largest salivary calculus on record, and as the report of the case has not, that I am aware of, been republished in this country, I quote it in full:

Salivary Calculus removed from the Orifice of the Parotid Duct. By John C. Thorowgood, M.D.*

J. K., aged seventy years, presented himself for treatment at the Hospital for Diseases of the Throat. An examination discovered a tumor of the size of a large walnut at the ramus of the inferior maxilla on the right side, very painful on pressure and accompanied with difficulty in deglutition and articulation, slight dyspnoea, and inability to open the mouth widely.

He gave his history as follows: The swelling was first noticed twelve years ago; there has been discharge of pus into the cavity of his mouth, and about four years ago an abscess pointed and discharged externally. He states that he has attended various hospitals, but the presence of the calculus was not detected, attention having only been directed to the external abscess and swelling.

Dr. Prosser James, on examining the mouth, observed a small white circular patch, about a fourth of an inch in diameter, lying external to and near the ramus of the inferior maxilla. When touched with the finger, acute pain was felt by the patient, and having arrived at the conclusion that it was a concretion, Dr. Prosser James, with the assistance of Dr. Clinton Wagner, proceeded to remove it by dividing the firm structures which grasped it by means of a curved bistoury and then withdrawing the mass with the forceps. The cavity in which it had lain was felt by the finger to be quite empty, and in a week the man came back expressing himself to be quite comfortable, able to take solid food, and beginning already, he thought, to regain some of his lost flesh.

The calculus now exhibited weighs ninety-three grains and a half, is an inch and an eighth long and two inches round, and is composed mainly of phosphate of calcium.

The Richmond Academy of Medicine and Surgery.—The special order for the next meeting, on Tuesday evening, the 14th inst., is a discussion on General Neuritis, to be opened by Dr. H. H. Levy.

THE RELATIONS OF THE HEART AND LUNGS TO THE ANTERIOR CHEST WALL, AS DETERMINED BY COMPOSITE PHOTOGRAPHY.*

By IRVING S. HAYNES, Ph. B., M. D.,

DEMONSTRATOR OF ANATOMY IN
THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK;
MEMBER OF THE SOCIETY OF THE ACADEMY OF MEDICAL SCIENCES,
OF THE NEW YORK COUNTY MEDICAL SOCIETY,
OF THE ASSOCIATION OF AMERICAN ANATOMISTS, ETC.

THE study of the relations of the heart and lungs to the anterior chest wall is of the utmost interest to us, not only as anatomists searching after the exact relations of the various parts of the human body, but also as surgeons and physicians engaged in the treatment of these organs in their various morbid states; for how can a departure from the normal relations of the body be detected unless we are familiar with those relations?

It is practically impossible to determine the surface relations of the heart and lungs in the living except in the most general way, and we are forced to study out the problem upon the cadaver.

After we have obtained our post-mortem measurements we can not apply them indiscriminately to the living individual. Due allowances must be made for the constantly changing positions of the heart and lungs with every pulsation of the former and respiration of the latter, for the changes caused by the different positions assumed by the individual or produced by the states (physiological or pathological) of the neighboring viscera (stomach, liver).

The varying thickness of the superficial tissues and the sexual peculiarities of the chest and mammary configuration must also be taken into account.

Notwithstanding all these difficulties with which we must contend, our post-mortem results do admit of the most practical application, and when the necessary corrections of age, sex, posture, etc., are made, become of such reliability as to deserve our confidence.

Of the methods heretofore employed for determining the surface positions of the heart and lungs I will speak briefly of two—namely, transfixion and frozen sections.

Transfixion by long pins is a method subject to many sources of error, and in the end becomes a good deal like guesswork; for, unless the differences between the positions of the pins and the actual position of the viscera under consideration are correctly taken and referred to corresponding points upon the chest, the results from this method will be too uncertain to be depended upon.

Frozen sections carefully made, as directed by Professor Thomas Dwight, will give correct results, but the method is very laborious, takes a great deal of time, can be used only at a certain season of the year, and then only in favorably situated places.

In the face of these difficulties and with the confusion of mind following a hasty comparison of the measurements given in some of the standard text-books, I cast about for some way of determining these relations for myself rapidly, accurately, easily, and without reference to place or season,

and thought of my camera as a faithful agent to fulfill these diverse requirements.

Composite photography has been applied to the solution of other problems, but I think I am the first to apply it to the determining of the external relations of the heart and lungs. I began my experiments in May, 1893, and would say in this connection that I have applied the same method to solving the abdominal relations with most satisfactory results, which I hope to be able to present to the society at some future occasion.

Before entering upon a description of composite chest photography I wish to digress for a moment to offer a few comments upon the text-book literature of the subject and to make a plea for greater exactness in such works.

I do not contend that the statements of the various authors must agree with one another—that is impossible from the very nature of the subject—but I wish to object to the sweeping general statement that on close study furnishes us with so very little reliable information. As an example of this style, I quote the following *verbatim* from a text-book of anatomy: "The heart lies upon the tendinous center of the diaphragm, its base presenting upward and backward, and its apex pointing at the junction of the fifth rib and cartilage." And this is all there is in the entire volume respecting the location of such an important organ as the heart.

Again, I wish to call attention to rules apparently so exact but really hiding many perplexities, and for the first illustration I shall quote with all respect from that storehouse of anatomical information, *Quain's Anatomy*, vol. ii, 9th American edition, page 493, the following: Speaking of the left border of the heart and where to draw its outline upon the chest, he says it is indicated by a "line from the third cartilage," etc. Now, the third cartilage is anywhere from an inch and a half to two inches and a half long and about three quarters of an inch wide. How can such an area be the starting point of a line?

One more: Quain and Gray both give the base of the heart as a line "drawn across the sternum on a level with the second costal cartilages." Might we not with propriety ask, Is the upper border, or the center, or the lower border of these cartilages meant?

Many errors in our books are excusable, but I offer that in text-books, primarily intended for students and designed to be as concise and accurate in statement as is consistent with brevity, serious omissions should not be covered by a few generalities, nor should "points" mean any dimension of length up to an inch, or of surface from its proper definition up to an area of one or two square inches.

Again, we meet with difficulties in the application of these statements, however accurate, to the individual. For while in a thin person it is easy enough to recognize cartilages and ribs, when these landmarks are covered with even a moderate layer of fat their recognition becomes uncertain, to say nothing of locating the costo-chondral and chondro-sternal articulations. If I might offer a plan to assist in fixing the relations of the thoracic viscera to the exterior of the chest in connection with the usual landmarks of sternum, ribs, cartilages, and their articulations,

* Abstract read before the Sections in Anatomy and General Surgery of the First Pan-American Medical Congress.

I would suggest that we start from the supra-sternal notch and mark the distance to below the ensiform along the median line in inches or centimetres, and the distance of points transversely to the right or left of this line to be given with the distance on the mid-sternal line (from the supra-sternal notch), from which the lateral lines are drawn.

For example, the apex point in Subject I is two inches and a quarter transversely to the left of the mid-sternal line at its seven-inch point—i. e., at the point seven inches from the supra-sternal notch.

No matter how thick the layer of adipose tissue is over the chest, and how obscure the cartilages and ribs in consequence become, the supra-sternal notch can always be accurately determined by the same manoeuvre, only reversed, by which the anterior superior iliac spine is fixed—namely, by carrying the thumb from above downward into the notch until it comes in firm contact with the upper margin of the sternum, and from this point make the downward measurement.

The measurements to right or left must always be made at right angles to the mid-sternal line.

Source of Error.—Of course all chest walls and their contained viscera do not have the same dimensions, and it would be obviously incorrect to apply the results obtained from a large subject directly to a small one, yet after the measurements for the average male and female adult are obtained these can be applied to the determining of similar points in the average person and the extremes of our scale in the one case to the extremes in the other.

Perhaps we can subsequently determine a certain ratio between the chest measurements and its circumference, or some other representative measurement that will help us to overcome the above source of error, but my experiments have not yet been sufficiently numerous to justify the formulation of any reliable suggestion in this connection.

Directions for taking the Composite Chest Photographs.—Place the subject perfectly horizontal and inject carefully through the carotid (right or left) a thin plaster mixture (colored if desired) to moderate fullness.

Some subjects should be used without the injection; but the injection, when moderately given and after it has firmly set, serves to maintain the heart in a fixed position and is consequently an advantage. Moreover, by distending the heart moderately, as is usually the case, its natural position in diastole will be closely approximated (Subject I); and in those instances where the injection does not fill the ventricles and they happen to remain firmly contracted, you will secure the heart in a state closely allied to its condition during systole (Subject II).

Locate the position of the nipples with reference to the ribs and the mid-sternal line as previously described, then carefully incise them through their center to the deep parts and mark such places with an aniline pencil so they may be found later on.

Remove all superficial tissue and muscles (pectorals and abdominal) over an area sufficiently large to expose the entire chest from above the clavicles to below the lower ribs—and from side to side—as far as the anterior axillary

lines. Expose the trachea, cut it in two below the thyreoid cartilage, insert a rubber tube into it, and connect with the bellows or pump.

Thoroughly clean the ribs, cartilages, sternum, external intercostal muscles, clavicles, and the origin of the sterno-cleido-mastoids.

Now place a narrow tape measure or a strip of white paper, upon which the inches have been marked, from the upper margin of the sternum (supra-sternal notch) along the middle line to below the ensiform appendix.

Upon each cartilage and rib indicate the distance in inches, measured transversely from the mid-sternal line, by narrow strips of paper as long as the cartilage or rib is wide and placed vertically upon the same to the number of four or five on either side of the middle line. These strips of paper will help very much in determining the position and direction of the various ribs and cartilages.

Set up the camera vertically over the subject, focus on the nipple points (indicated by small circles of white paper), and fix the focus with the set-screw.

You will need two double plate holders, A and B, and very slow plates, numbering the slides A, 1 and 2, B, 1 and 2.

Take the chest in expiration on plates A, 1 and 2 (expiration, first exposure). The time of this exposure must bear the ratio to the full exposure of about one to three.

Inflate the lungs to moderate distention, counting the number of bellows or pumpfuls, and expose plates B, 1 and 2 (inspiration, first exposure). Let the air escape from the lungs.

Remove the sternum from the lower level of the first cartilage to the upper of the seventh, the included cartilages and ribs for a distance of four to five inches from the median line. Do not open the pleure.

Now inflate the lungs with the same number of bellows or pumpfuls as before.

Expose B, 1 (inspiration, second exposure, pleure not opened). Open the pleural sacs and remove their anterior portions. Expose B, 2 (inspiration, second exposure, pleure removed). Allow the air to escape from the lungs. Expose A, 1 (expiration, second exposure, pericardium intact). Remove the presenting portion of pericardium from heart and great vessels. Expose A, 2 (expiration, second exposure, pericardium removed).

These photographs* will give you the position of the lungs, with and without their pleure, and of the heart, with and without its pericardium, upon the chest wall, from which the necessary measurements can be accurately determined.

By the preceding method the following relations were obtained.

SUBJECT I.—Adult, male, negro, apparently about thirty-five years of age. Cause of death unknown. Subject

* When a border of the heart or lungs is said to cross a cartilage or intercostal space at a certain distance from the median line, the measurement is always made from the center of the cartilage or space, unless otherwise stated.

had been injected with chloride of zinc and starch-colored mixture originally for another purpose, but was used for this experiment.

A. *Nipples*.—Located over the lower half of the fourth rib, three inches and a half transversely from the mid-sternal line (and at a point on that line five inches from the supra-sternal notch); both alike.

B. *Heart*.—This organ had been distended by the injection and approximately represented the heart in diastole. Its relations were as follows:

1. *Base*: This is taken as the upper limit of the heart. It is indicated by a line drawn across the sternum from just below the middle of the second intercostal space on the right side an inch and a quarter from the mid-sternal line (at its three-inch point) to the left to cross the median line (at the two-and-three-quarter-inch point) and end at the upper portion of the second left space an inch and a half from the mid-sternal line (opposite its two-and-five-eighth-inch point).

2. *Apex*: Behind the center of the fifth interspace two and a quarter inches to the left of the median line (at its seven-inch point.)

3. *Left Border*: From the left extremity of the base line downward and slightly outward to cross the third costal cartilage two inches from the mid-sternal line (at its three-and-five-eighth-inch point). It continues downward and outward until the fourth interspace is reached, then turns inward as it passes to the apex point.

This line crosses the fourth left costo-chondral articulation, which is two inches and three quarters from the mid-sternal line (opposite its five-inch point), the fourth interspace, at the center of which it is two inches and seven-eighths from the mid-sternal line (at its six-inch point); from here it curves downward and inward, crosses the fifth cartilage two inches and three-quarters from mid the sternal line (opposite the six-and-five-eighth inch point), and ends at the apex (see 2).

4. *Right Border*: Begins at the right end of the base line, passes outward and downward across the third right costal cartilage an inch and a half from the mid sternal line (at its three-inch-and-a-half point), over the third interspace and fourth costal cartilage an inch and three quarters from the mid-sternal line (the former opposite the four-and-three-eighth and the latter the five-inch points respectively). It now curves downward and inward and terminates over the center of the fifth costal cartilage an inch and three eighths from the median line (at its six-inch point).

5. *Lower Border*: This joins the lower ends of the right and left borders. In doing so it describes a wavy course  with a concavity at each end, looking upward, and one in the center, as it crosses the middle line, looking downward. It crosses the sixth and seventh right costal cartilages transversely to their long axes, the median line at its six-and-three-quarter-inch point, over the middle of the ensiform, and the seventh left costal cartilage very obliquely to reach its lowest point at the lower margin of the sixth costal cartilage an inch and a quarter to the left of the mid-sternal line (at its seven-and-a-half-

inch point), then turns abruptly upward to join the lower extremity of the left border at the apex.

C. *Auricles*.—1. *Right*: Its upper and outer (right) borders are formed by the portions of the base and right border lines of the heart, cut off by a line which forms the inner (left) border of the auricle and which starts from the base line a quarter of an inch to the right of the median line and passes directly down until opposite the lower border of the third right costal cartilage (at the three-and-five-eighth-inch point on the mid-sternal line). From this point it curves slightly downward, passing outward about parallel with the lower margin of the third costal cartilage until an inch from the mid-sternal line (opposite the four-inch point), when it turns more abruptly downward and intersects the right border of the heart at the upper margin of the fourth costal cartilage.

2. *Left*: This shows as only a very small, half-moon shaped space, bounded above and on the outside by small adjacent portions of the base and left border of the heart. Its inner margin is indicated by a line drawn from a point on the base line an inch to the left of the mid-sternal line, and curving downward and outward to intersect the left border, where it crosses the center of the third cartilage.

D. *Auriculo-ventricular Groove*.—The two extremities of the line indicating this groove correspond to the lower halves of the inner borders of the auricles; the central portion, to a line connecting the middle points of these borders and curving slightly upward as it crosses the sternum.

E. *Coronary Arteries*.—1. *Right*: Runs from the middle point of the inner boundary of the right auricle, an inch from the median line, downward in a nearly straight course to the lower border of the heart, three quarters of an inch from the mid-sternal line.

2. *Left*: This begins similarly at the mid-point of the inner margin of the left auricle, and descends almost vertically and about an inch and a quarter from the mid-sternal line to the lowest point of the lower border of the heart.

F. *Long Axis of the Heart*.—Reaches from the right end of the base line to the apex. It crosses the mid-sternal line (at its four-and-a-half-inch point) opposite the centers of the sternal ends of the fourth cartilages.

G. *Area of Cardiac Dullness during Inspiration*.—It is a quadrilateral space, bounded on the right by the median line, below by the lower border of the heart, above by a line drawn from a point on the mid-sternal line (four-and-a-half-inch point) opposite the centers of the sternal ends of the fourth cartilages, along the upper margin of the fifth left cartilage, an inch and a quarter from the mid-sternal line (opposite its five-and-three-quarter-inch point), and on the left by a line from the last point downward and inward to cross the lower border of the heart, three quarters of an inch to the left of the median line.

Roughly stated, this area is an inch and a quarter wide, to the left of the median line, limited above by the upper margin of the fifth left cartilage, and below by the lower border of the heart.

H. *Aorta*.—Its axis corresponds to the median line as far as it is shown in the photograph, its right border being

half an inch to the right of its left, the same distance to the left of the median line, the former reaching from the base line (half an inch to the right of the mid-sternal line), and the latter appearing above the pulmonary artery, and both disappearing under the upper fragment of the sternum.

I. Pulmonary Artery.—This occupies the intervening space between the auricles, and is limited below by the line for the auriculo-ventricular groove. It is about an inch and a quarter wide at its base, and extends above the base line about half an inch, where it disappears under the aorta. It conceals the origin of the left portion of the aorta.

J. Superior Vena Cava.—This shows as nearly vertical and three quarters of an inch wide along the right side of the aorta. Its right border begins from the point of intersection of the right heart border and the upper margin of the third costal cartilage, and passes directly upward to disappear under the upper sternal fragment. Its left border is indicated by the same line as the right margin of the aorta.

K. Lungs.—In inspiration (moderately inflated) and contained within the unopened pleuræ. Their anterior edges alone traced.

1. Right: The anterior border of the right lung is nearly vertical for a considerable part of its extent.

It appears (in the photograph) issuing from beneath the upper fragment of the sternum, opposite the one-and-a-half-inch point of the mid-sternal line, and distant from it half an inch to the right. It passes downward and inward to cross the mid-sternal line at its one-and-three-quarter-inch point (opposite the first interspaces), and reaches a quarter of an inch beyond the center line toward the left.

From here it descends vertically parallel with and a quarter of an inch from the middle line until on a level with the center of the sternal ends of the fifth cartilages (opposite the five-inch point on the mid-sternal line), where it turns to the right, crosses the median line, and passes downward and outward, following the direction of the upper margin of the sixth cartilage.

2. Left: Its outline is more irregular than the right, as it has a large notch for the accommodation of the heart.

Like the right, it comes out from the upper portion of the sternum, the same distance to the left of the mid-sternal line, at the same point (one-and-a-half-inch point), passes downward toward the right, and meets the right lung on a level with the upper border of the second costal cartilages (opposite the two-inch point on the mid-sternal line).

From here the inner borders of the two lungs (separated only by the pleuræ) remain in close contact until opposite the middle point between the fourth cartilages (four-and-a-half-inch point on the mid-sternal line), when the left lung abruptly leaves the other and passes outward and downward parallel with the upper border of the fifth costal cartilage until an inch and a quarter from the mid-sternal line (opposite its five-and-three-quarter-inch point). It now passes downward and slightly inward until the sixth cartilage is reached, which it follows outward to the left along its upper margin.

3. This notch in the left lung exposes the lower portion of the heart, and forms the upper and outer boundary of the area of the heart exposed in inspiration. The inner border of this space agrees with the median line, and its lower with the lower margin of the heart.

SUBJECT II.—Adult male, white, about forty-five years of age; cause of death unknown. Subject had been injected with zinc chloride and plaster color mixture.

A. Nipples.—These are situated three inches and a half from the median line on the extreme lower margin of the fourth ribs. As the left ribs slope down slightly further than the right, it follows that when referred to the median line the left nipple is a quarter of an inch lower than the right (or the left is opposite the five-and-a-quarter-inch point and the right opposite the five-inch point on the mid-sternal line).

B. Heart.—The auricles and aorta were injected, but the ventricles were not, and were in a state of firm contraction, and so represent fairly accurately the position of the heart in systole.

1. Base: This is indicated by a line from just above the upper margin of the third right costal cartilage, an inch and five eighths from the mid-sternal line (at its three-and-a-half inch point), drawn across the sternum to end three quarters of an inch to the left of the median line opposite the center of the second interspace (at three-and-a-quarter-inch point on mid-sternal line).

2. Apex: Over the center of the seventh left costal cartilage three quarters of an inch from the median line (opposite its seven-and-a-half-inch point).

3. Left Border: From the left extremity of the base, nearly vertically downward to the apex point.

It crosses the cartilages of the third, fourth, fifth, and sixth ribs at a distance of seven eighths of an inch from the mid sternal line, opposite the following points on this line: The third, at the three-and-seven-eighths-inch point; the fourth, at the five-inch point; the fifth, at the six-inch point; the sixth, at the seven-inch point.

4. Right Border: From the right extremity of the base line downward and slightly outward to the middle of the fourth costal cartilage, an inch and three quarters to the right of the mid-sternal line at its five-inch point. In crossing the third cartilage it is an inch and five eighths from the same line (at its three-and-seven-eighths-inch point). The line now passes downward and inward to the center of the fifth cartilage an inch from the mid-sternal line opposite the six-inch point.

5. Lower Border: Really continues the direction of the right border from the last point above downward and inward in a nearly straight direction to cross the median line at its seven-and-a-half-inch point. Over the xiphi-sternal articulation to the left of the median line it descends a slight distance as it passes outward until about three quarters of an inch from the same, when it turns upward to the apex and joins the lower extremity of the left border. This line is slightly concave downward and toward the right as it crosses the sixth and seventh right cartilages.

C. Auricles.—1. Right: Presents a pear-shaped outline in the photograph, its upper and outer margins being

formed by the adjoining parts of the base and right border of the heart. Its inner boundary is indicated by a line from the base, half an inch to the right of the median line, passes vertically downward for three quarters of an inch, then downward and outward to intersect the right border, where it crosses the upper margin of the fourth costal cartilage.

2. Left: Shows as the merest oval space in the angle of the base line and left border and limited on the inside by a line drawn downward and outward from a point on the base half an inch to the left of the median line to the left border at the lower margin of the third costal cartilage.

D. *Auriculo-ventricular Groove*.—This is indicated at either extremity by the lower portions of the inner auricular margins, and its central portion by joining these two extremities by a line slightly convex upward as it crosses the mid-sternal line (at its four-inch point) opposite the lower margin of the third costal cartilages.

E. *Coronary Arteries*.—1. Right: This comes out from under the lower and middle thirds of the inner border of the right auricle nearly an inch to the right of the median line, and with many turns and twists, due to the contracted state of the heart, passes downward nearly vertically to the lower border of the heart.

2. Left: This shows on the extreme left of the heart issuing from the lower portion of the inner margin of the left auricle and descending directly to the apex, varying in its distance from the left of the median from three quarters of an inch in the upper third to half an inch in the lower third of its course.

F. *Long Axis of the Heart*.—From a point on the base an inch and a quarter to the right of the median line to the apex. This crosses the middle of the sternum (opposite the six-inch point) on a level with the lower border of the fifth cartilages.

G. *Area of Heart exposed in Inspiration*.—Owing to the contracted state of the heart, its entire lower portion to the left of the mid-sternal line and below the lower border of the fourth cartilage is uncovered.

H. *Aorta*.—Right Border: This is shown by a line from the right extremity of the base drawn vertically upward across the second costal cartilage an inch and three quarters from the mid-sternal line (at its two-and-three-quarter-inch point), then curves upward and toward the left to pass under the upper sternal fragment an inch and a half from the mid-sternal line (at the two-inch point). The left border is covered at its beginning by the pulmonary artery and only shows as a short curved line reaching from the level of the lower margin of the second right costal cartilage a quarter of an inch from the median line (at its three-inch point) toward the left to cross the mid-sternal line on a level with the upper margin of the second costal cartilages (at the two-and-a-quarter-inch point.)

I. *Pulmonary Artery*.—Occupies the interauricular space; with this it passes upward, curving toward the left, and disappears on a level with the upper border of the second cartilages.

J. *Superior Vena Cava*.—Does not appear in the photograph.

K. *Lungs*.—In inspiration (moderately inflated) inclosed within the unopened pleural sacs.

1. Right: Appears from under the upper fragment of the sternum an inch to the right of the mid-sternal line (at its one-and-a-half-inch point), passes downward and inward, crosses the middle line (at its two-and-a-half-inch point), opposite the upper border of the second cartilages, continues its course to about a quarter of an inch to the left of the median line, and then descends nearly parallel with the same and at an average distance from it of a quarter of an inch until opposite the upper margin of the sixth costal cartilages (at the six-and-a-half-inch point on the mid-sternal line) it bends to the right, crosses the mid-sternal line (at its six-and-three-quarter-inch point), and runs outward and downward parallel with the upper margin of the seventh costal cartilage.

2. Left: This issues an inch to the left of the median line opposite the same point (an inch and a half) as the right, inclines downward and inward until at the lower margin of the second costal cartilage (left) it takes a course parallel with and nearly half an inch from the left of the mid-sternal line, until just below the lower border of the fourth left cartilage (at its five-and-three-eighth-inch point on mid-sternal line), where it turns transversely outward for half an inch, then downward and outward to the fifth intercostal space an inch from the mid-sternal line (at its six-and-three-quarter-inch point). It now bends inward to meet the upper margin of the seventh costal cartilage, then turns outward along the upper margin of the same.

The two lungs come in contact for only a quarter of an inch opposite the lower margin of the third cartilage.

3. The amount of heart uncovered by the left lung is in this case an area at the left of the median line an inch wide and nearly two inches long, reaching from the lower border of the fourth to that of the sixth left cartilage.

SUBJECT III.—Adult female, white, about twenty-five years old, well formed and quite muscular. Probable cause of death, pneumonia (double). Subject was not injected.

A different plan was followed in this instance from that in the two preceding cases.

The subject was firmly strapped to a tilting table and suspended by the neck in a nearly vertical position. The camera was adjusted, focused, and set. Then negatives of the chest (before and after dissection), of the heart (with and without the pericardium), and of the lungs were made without disturbing the subject or camera, and these negatives fit upon each other perfectly, so that, after prints were made, the measurements were obtained by placing the photograph of the heart or lungs over that of the exterior of the thorax and tracing upon the latter the outlines of the former by pricking through the two with a pin.

This method gives good results, provided no change of focus or of the position of subject or camera is made, as the images of the deeper structures are not obscured by those of the more superficial ones. Perfect outlines of the heart with its vessels and of the lungs can be obtained by tracing them as above shown.

A. *Nipples*.—The breasts were small (for a female of this size) and firm.

1. Right: In the center of the fourth interspace four inches from the mid-sternal line (opposite its five-and-a-quarter-inch mark).

2. Left: Over the lower margin of the fourth rib, four inches from the mid-sternal line (at the same point as above).

The ribs on the left side curve downward slightly more than on the right, and this accounts for the different relations of the two nipples with reference to the thoracic wall. Referred to the median line, they are exactly on the same level.

B. *Heart*.—This organ with its vessels was only moderately distended with blood.

1. Base: Begins in the center of the third interspace an inch and an eighth to the right of the mid-sternal line (at its four-inch point), curves slightly upward as it passes to the left to cross the median line (at its three-and-a-half-inch point), on a level with the lower border of the third costal cartilages, and ends an inch and a half to the left of the mid-sternal line (at its three-and-a-quarter-inch point) at the upper margin of the third costal cartilage.

2. Apex: The apex point is over the interchondral articulation of the cartilages of the fifth and sixth left ribs an inch and a half from the mid-sternal line (at its seven-and-a-half-inch point).

3. Left Border: Begins at the left extremity of the base line, passes downward, inclining slightly outward, until the middle of the fourth interspace is reached, two inches from the mid-sternal line (at its six-and-a-quarter-inch point). From here it turns downward and toward the right to end at the apex point.

The left border crosses the third costal cartilage an inch and a half from the mid-sternal line (at the three-and-three-quarter-inch point), the fourth cartilage two inches from the same (at the five-and-a-half-inch point), and the fifth cartilage an inch and three quarters (at the six-and-seven-eighth-inch point).

4. Right Border: Extends from the right extremity of the base line vertically downward to the center of the sixth costal cartilage an inch from the mid-sternal line (at its six-and-a-quarter-inch point). This border crosses the fourth and fifth cartilages at the same distance from the median line (the former opposite the four-and-a-half and the latter the five-and-a-half-inch points).

5. Lower Border: Is indicated by a line from the lower end of the right border downward and toward the left to cross the seventh right cartilage transversely to its long axis, the mid-sternal line (at its seven-and-a-quarter-inch point), over the middle of the ensiform, continues still downward and outward to the center of the sixth left costal cartilage an inch from the mid-sternal line (at its seven-and-a-half-inch point), then curves upward to end at the apex point and connect with the lower end of the left border. This line is slightly concave upward and to the left as it crosses the median line.

C. *Auricles*.—1. Right: The inner border of the right auricle is indicated by a line which starts from the base a quarter of an inch to the left of the mid-sternal line,

passes vertically downward until opposite the middle of the sternal ends of the fourth cartilages (at the four-and-a-quarter inch point of the mid-sternal line), where it turns toward the right across the median line (at its four-and-three-eighth-inch point), then, with a slight convexity toward the right shoulder, passes to meet the right border of the heart as it crosses the lower margin of the fifth costal cartilage. The auricle is bounded on its upper and outer sides by the adjoining portions of the base and right border of the heart.

In this case the auricle reaches to the left a quarter of an inch beyond the median line.

2. Left: This is a very small space cut off at the angle of junction of the base and left border by a line beginning seven eighths of an inch to the left of the mid-sternal line on the base line, and passing downward and outward to meet the left border at the lower margin of the third costal cartilage.

D. *Auriculo-ventricular Groove*.—Corresponds to a line joining the middle points of the inner auricular boundaries plus the lower halves of these borders.

E. *Coronary Arteries*.—1. Right: Issues from the inner border of the right auricle, half an inch to the right of the mid-sternal line, and passes downward and inward to the lower margin of the heart at the median line.

2. Left: This issues from the inner border of the left auricle, an inch and a quarter from the mid-sternal line, and passes vertically downward until near the apex, when it turns inward to reach the lower border, half an inch to the left of the median line.

F. *Long Axis of the Heart*.—From the base line, three quarters of an inch to the right of the mid-sternal line, to the apex point, it crosses the median line (at its four-and-three-quarter-inch point) opposite the upper border of the fifth cartilages.

G. *Area of Heart exposed in Inspiration was not determined, owing to the Condition of the Lungs*.—In expiration the lungs collapsed. The entire lower two thirds of the heart to the left of the median line and below the level of the upper margin of the fourth costal cartilage is exposed.

H. *Aorta*.—In width, as shown in the photograph, is about an inch. Its right border starts from the base an inch to the right of the mid-sternal line and passes upward across the third cartilage, seven eighths of an inch from the median line (at the three-and-a-half-inch point), across the second cartilage five eighths of an inch from the central line (at the two-inch point), and is lost curving toward the left under the upper sternal fragment.

Its left border shows only for a short distance curving over the pulmonary artery from right to left, about an inch from and parallel with the right border.

I. *Pulmonary Artery*.—Includes the space left between the auricles and also comes from behind the entire inner half of the left auricle. It reaches as high as the lower margin of the second costal cartilage (opposite the two-and-a-quarter-inch point on the mid-sternal line).

J. *Superior Vena Cava*.—Shows in a collapsed state to the right of the aorta. Its right border reaches from the extreme right end of the base vertically upward to disap-

pear under the upper sternal fragment and cartilage of first rib. Its left margin is the same as the right for the aorta.

K. *Lungs*.—These could not be inflated satisfactorily (death due to a double pneumonia), so no attempt at securing photographs of them in *inspiration* was made.

The following measurements give the outlines of the anterior margins of the lungs in their partially collapsed state—pleura removed.

1. Right: The anterior border appears above in the median line (at the one-and-a-half-inch point), passes downward and to the left of the mid-sternal line until opposite the center of the second interspace (at the two-and-a-half-inch point on the mid-sternal line and a quarter of an inch to its left), runs parallel with the median line until (opposite its three-and-three-fourth-inch point) on a level with the center of the third space, when it curves downward and toward the right and is lost running parallel with the upper margin of the sixth costal cartilage.

2. Left: Issues from the upper sternal fragment three eighths of an inch to the left of the mid-sternal line (at the same one-and-a-half-inch point as above), descends, almost touching the right lung, until opposite (the three-and-a-half-inch point on the mid-sternal line) the lower border of the third cartilage, it turns outward toward the left along the upper margin of the fourth costal cartilage until it reaches the left border of the heart, which it follows to near the apex, then turns to the left, following the curve of the sixth costal cartilage (upper margin).

3. Area of heart exposed on expiration: See Sec. G preceding.

(To be concluded.)

TRAUMATIC DEAFNESS.

By W. H. BATES, M.D.,

ASSISTANT SURGEON, NEW YORK EYE INFIRMARY.

SEVERAL years ago a case of traumatic deafness was treated. Both drum membranes were ruptured by an explosion of dynamite. The tuning-fork test showed symptoms of nerve deafness. Treatment consisted in careful cleansing of the middle ear, politization, and the use of general tonics. A successful effort was made to prevent the margins of the perforations from becoming adherent to the promontory. The patient's hearing became more acute than before the injury, possibly from the fact that the cicatrix tightened the drum membrane. A number of other persons injured at the same time by the explosion to about the same degree, not treated, did not recover their hearing. Of the following cases reported, Case VI was the only one to receive treatment, and was the only one which was observed to end in recovery. Cases of traumatic deafness with rupture of the drum membrane need immediate treatment. Methods of treatment which are beneficial in middle-ear disease from catarrhal inflammation are beneficial in traumatic deafness. Politization early in the treatment may not benefit, but will improve the hearing after the drum membrane has healed.

The following cases are interesting, as showing the

variety of injury capable of causing deafness. All were in dispensary patients:

CASE I.—J. G., aged eighteen years, was kicked by a horse on the end of his chin. He was unconscious ten minutes. The injury occurred June 22, 1891. The patient was seen the next day. Both drum membranes were ruptured. The left ear bled all night. A clot fills the left external auditory canal. Ears pain on swallowing. Right, watch, $\frac{2'}{48''}$; left, watch heard only on contact.

CASE II.—C. B., aged thirty-five years, fell from a ladder in December, 1891, and struck the back of his head. Sudden deafness, complete in both ears, occurred immediately. Three days later hearing returned partially in the right ear. March 31, 1892, the patient came to the dispensary. Drum membranes of both ears are sunken, pale-yellow in color; the malleus handle is red, prominent, not displaced forward or backward. Tinnitus is complained of in both ears, and it is worse in the right ear, which is the ear with the better hearing. There is an appearance of a cicatrix in the lower portion of both drum membranes (healed traumatic rupture of the membranes?). During inflation air rushes through the Eustachian tubes and produces a sound like the sound of a dry tube opening and allowing air to enter. Paralysis of the seventh nerve on the left side, but it is not complete. Right, acoumeter, $\frac{6''}{100'}$; left, acoumeter, 0. After inflation, right, acoumeter, $\frac{8''}{100'}$; left, acoumeter, $\frac{c}{100}$.

The case is interesting from the fact that inflation improved the hearing.

CASE III.—R. S., aged forty-seven years, fell down stairs. There was a discharge of blood at the same time from both ears. Collar bone was broken. Tinnitus began at once.

December 12, 1891, six weeks after the injury, presented himself for treatment. Both drum membranes healed with the appearance of a cicatrix in the posterior portion of each drum membrane. The patient complains of dizziness. The tinnitus is still annoying. Ordered tincture of iron, 3 ss., three times a day.

December 22d.—He has less dizziness.

December 29th.—Right, watch, $\frac{4'}{48''}$; left, acoumeter, $\frac{1''}{100'}$.

Politization improves the hearing of both ears.

CASE IV.—J. L., aged twenty-six years. While loading a truck on August 1, 1892, a barrel fell against his head. He came to the dispensary three days later complaining of deafness. Right drum membrane has a circular perforation below the apex of the malleus handle. There is a slight bloody discharge from the right ear. The left drum membrane is congested; it is not ruptured. Right, acoumeter, $\frac{2'}{100'}$; left, watch, $\frac{6''}{48''}$.

CASE V.—W. D., aged sixty-two years, was seen November 1, 1892. During the War of the Rebellion, while standing near the muzzle of a gun at the time of its discharge, he felt a sudden pain in his right ear, which seemed to go through his head to his left ear. The right ear was deaf from that time. He noticed no discharge from either ear. Right, watch heard on pressure against the ear. Left, watch, $\frac{12''}{48''}$.

CASE VI.—F. V., aged twenty-two years, while bathing, August 19, 1893, was struck on the left side of his head by the

shoulder of a companion diving from a height of about six feet. The left ear immediately discharged fluid and blood. About an hour after the injury he noticed tinnitus which continued without intermission.

August 22d.—The patient began treatment. Right ear is normal. The left ear hears watch, $\frac{2''}{48''}$. The left drum mem-

brane is perforated in the posterior inferior quadrant. There is considerable redness and swelling of the drum membrane. Ordered syringing with warm saturated solution of boric acid.

September 5th.—The drum-membrane perforation has healed. Left, watch, $\frac{6''}{48''}$. Politization did not improve the hearing. R Ung. flav., gr. xx- $\frac{3}{4}$ j, to be applied in the external auditory canal.

September 19th.—Left, watch heard at 3". After politization the hearing improved to 5". There is now no tinnitus.

September 23d.—Left, watch, $\frac{6''}{48''}$. Politization did not improve the hearing.

October 3d.—Left, watch, $\frac{20''}{48''}$; after politization the hearing improved to nearly normal. The tinnitus has not returned. Hearing for conversation seems good.

64 EAST FIFTY-EIGHTH STREET.

A NEW BANDAGE FOR THE TREATMENT AFTER THIERSCH'S METHOD OF TRANSPLANTATION OF SKIN.*

By OSCAR J. MAYER, M. D.,

SAN FRANCISCO, CAL.

LATE ASSISTANT ON THE SURGICAL STAFF OF MOABIT HOSPITAL, BERLIN.

THE method of transplanting skin first introduced into medicine by Professor Thiersch enjoys such universal employment—possessing as it does advantages recognized on all sides—that it appears hardly necessary to here employ space stating its uses. Not alone can the surgeon with a host of skilled assistants at his side make use of this procedure for a patient's benefit, but as well the ordinary coun-

ent are in the removal either loosened or else wholly torn away.

By means of the dry bandage, which remains five to six days, we—on extensive surfaces, for example—are rewarded, on an average, with the firm adhesion of about sixty per cent. of the transplanted pieces. With the moist band-

age, with or without silk protective, whether using liquor aluminii acetatis or an ointment, even with the most painstaking care, on removal of the bandage we find that some pieces are torn away, while others are loosened to such an extent that they go over into necrosis and fall away.

In consequence, I have made an attempt to overcome this difficulty by means of an alteration in the bandage. After the transplantation the bandage is so applied that contact with the wound or surrounding surface is avoided, the wounded surface being bridged over.

As one can readily see from Fig. 1, a pillow of wool, cotton, or like material is placed one above and one below the surface operated upon. If the pillow is now bridged over by a slat of wood or firm pasteboard, and the whole made into a bandage *lege artis* and still further stiffened by a starch bandage, we shall have the wound well covered, yet contact can take place at no point. The bandage can be changed as often as necessary without disturbing the transplanted pieces—a self-evident advantage in this operation.

As, however, on extensive surfaces—for example, in ulcerations on the leg or arm, encircling the whole limb—a broad slat would not be practicable, whereas many narrow ones would present difficulties and require assistance, I have devised an arrangement by which small slats, cut appropriately, are pasted upon a piece of linen parallel and close to each other, so that the whole can be rolled, as can be easily seen from Fig. 2.

As this bandage does not sit firmly over ulcerated surfaces in the region of the elbow joint or of the dorsum of the foot, I have made use of strips of plaster of Paris modeled appropriately and likewise resting on pillows (*vide* Fig. 3). This latter method can be used with great advantage when transplanting is resorted to for covering extensive burns of the chest, back, or other regions of the body.

As a matter of course, the plaster strips must be modeled with due reference to the location for which they may

try practitioner, who is thrown entirely on his own resources for assistance.

Only the after-treatment presents some objectionable difficulties, in so far as the oft-necessary change of bandage has as a consequence that pieces already somewhat adher-

* Read before the Section in Surgery of the First Pan-American Medical Congress.

be designed, so that they cause neither pressure nor other untoward symptoms.

One disadvantage has shown itself in this method, and must not be overlooked. In the operation of transplanting it sometimes happens that small pieces of the transplanted skin lap over on to the healthy skin or upon one another. These overlapping pieces form small vesicles within the next twenty-four hours. These must be opened and the overlapping pieces carefully removed, when, if the granulating surface has been aseptic, a serum-like fluid, in not aseptic condition a sero-purulent fluid or pus, exudes. In the transplantations which I have carried on antiseptis was not employed further than in *preparing* the field of operation. The pieces of skin were removed with a knife

dipped into a sterilized 0.6-per-cent. salt solution, and immediately placed upon the granulating surface, paying par-

ticular attention that none of the pieces might overlap. After being bandaged from four to five days with the flat bandage, the transplanted pieces were so firmly attached that further treatment could be continued by means of a liquor-alumini-acetatis dressing, which could be removed without danger of loosening or tearing away the small pieces of transplanted skin.

The above-mentioned disadvantage which may occur with this method of bandaging is so slight in comparison to the great advantages which the method offers that I may hope that the medical profession in general may obtain the same good results, and in making use of it save much time and labor.

801 SUTTER STREET.

The Death of Dr. Charles Frederick Crehore, of Newton Lower Falls, Mass., took place on Wednesday, the 8th inst. He was a graduate of the Harvard Medical School, of the class of 1854. Nearly thirty years ago he gave up the practice of medicine and engaged in a manufacturing business. During the War of the Rebellion he served as a medical officer in the army.

Dr. Keeley's Suit against the Lancet.—The *Lancet* announces that Dr. Leslie E. Keeley, of "gold-cure" notoriety, has discontinued the suit for libel brought by him against the editors of that journal, and will be obliged to pay the costs.

THE NEW YORK MEDICAL JOURNAL.

A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, NOVEMBER 11, 1893.

"RAILWAY SPINE."

DR. LOUIS BAUER, of St. Louis, has given in the *Clinique*, of that city, reasons which in his mind weigh against the use of the term at the head of this article. He considers the term, which owes its origin to the eminent Mr. Erichsen, an unhappy one, for the reason, chiefly, that it presents no definition and has no scientific significance. It has undoubtedly contributed to a multitude of actions for damages and set at variance many experts in all parts of the English-speaking world. The attention of investigators has been diverted by it from the real

"traumatic neurosis" as a subject of experimental and clinical research; otherwise long before now the pathological significance of that neurosis would have been better understood.

The diligent labors of Dr. H. Schmaus, recorded in the *Archiv für pathologische Anatomie und Physiologie und für klinische Medizin* for 1890, have already promoted a clearer appreciation of the subject.

By subjecting dogs to a series of traumatic forces bearing upon their spinal columns, Schmaus has induced a variety of injuries to the cord, its coverings, the exterior muscular apparatus, and the peripheral nerves of the spinal region. In a certain number of cases the same violent acts left no impression upon the parts exposed to them. He likewise was able to affirm that when anatomical lesions were inflicted they were as a rule responded to by appropriate symptoms. We learn from these discriminating experiments of Schmaus's to look upon contusion and concussion, respectively, as the proximate causes of widely different morbid effects. The former is the source of the ordinary anatomical derangements, while the latter responds to Oppenheim's definition of "traumatic neurosis." As to the *modus operandi* of spinal concussion as the parent of grave cases of suffering, enduring even for a term of years, Dr. Bauer is not in agreement with Oppenheim; Dr. Bauer relates an instance, observed in his own practice, the duration of which exceeded a third of a century. He holds that the large majority of the more estimable or trustworthy part of the profession take emphatic exception to Oppenheim's views, and thinks that Oppenheim's admissions afford substantial ground for those exceptions. For example, he owns that, in spite of the great violence of their suffering, the patients very seldom succumb, and commonly when the trial is over become materially improved "because their minds are set at ease."

Dr. Bauer also adverts to a recent article by Dr. Nonne, in

the *Deutsche medicinische Wochenschrift*, Nos. 27-29, 1893, in which the author states that most of the symptoms observed by him in certain cases could just as well pass as evidence of the traumatic neurosis—as estimated by Oppenheim—or as evidence of hysteria or neurasthenia, or signify cerebral or spinal lesions.

MINOR PARAGRAPHS.

NEWSPAPER MEDICINE AGAIN.

A WRITER in the *St. Louis Globe-Democrat* has soared above the mere blundering to which newspaper writers usually confine themselves when they descant on medical matters. In an account of an operation for traumatic aneurysm of the femoral artery, he says that the surgeon "cut a heart out of a man's leg." He goes on as follows: "Instead of being necessary to the patient's existence, as hearts usually are, this organ was a very dangerous possession and was likely to end his life at any moment. The heart was almost as large as the one usually found inside a man's ribs, and beat in very much the same manner. It was situated upon the inside of the right leg, four or five inches above the knee, and was more tender than the ball of the owner's eye. . . . The aneurysm could be seen to beat to all intents and purposes like any other heart. If one brought his ear close to it he could hear a constantly repeated blowing or breathing sound coming from beneath the skin. *This noise was caused by the vacant air space around the swollen artery where it had crowded the muscles aside.*" The operation is described thus: "A sharp knife laid the tissues aside and exposed the femoral artery with its apple-shaped bulb. The artery was then tied, or 'ligated,' two inches above and two inches below the swelling, and the big bulb cut open. Nearly a pint of blood gushed forth and then there was no heart left. The slit artery was then sewed together with fine-silk threads previously soaked in antiseptic solutions, and left to heal. The ligatures above and below were left to remain, however, until the artery is fully healed. Then they will be untied and the blood allowed to go down Gentry's [that was the patient's name] leg as usual. In the mean time the patient's limb will receive blood from the smaller arteries, and will in all probability keep from dying."

THE OHIO STATE ASYLUM FOR EPILEPSY.

GOVERNOR MCKINLEY has declared open the new retreat for epileptics at Gallipolis. The trustees are ready to receive two hundred and fifty male patients, but they are not fully provided with the proper information to enable them to classify the applicants for admission. Dr. H. C. Rutter, who is the medical officer, may be addressed at the asylum at Gallipolis. The blank forms of application are in the custody of the probate court of each county, and those who seek the benefits of the new institution are desired to call upon the probate judge and fill out the regularly prepared papers.

THE AMBULANCE STREET CAR.

THE application of the modern system of ambulances to electric street railways has been attempted in St. Louis. It results in the establishment of an emergency ward on car-wheels. The springs of the car are so made as to reduce to a minimum all the jar and shock that are apt to occur to the patient during transit. As three large hospitals and the chief dispensary of the city are located along the line of the electric roads, it will be convenient to convey the sick and injured from central districts, as well as outlying ones, by means of the elec-

tric-car ambulance. The ordinary city ambulances, moved by horse power, will still be required to supplement the work of the car ambulance. Every electric-car company in our cities should include an ambulance as a part of the original plant for this reason, if for none other, that a large casualty list is apt to accompany the establishment of electrical rapid transit in any crowded district. The companies should be prepared to help in the relief of those unfortunate citizens who suffer at the hands of inexperienced motormen and deranged machinery.

A NEW MEDICAL NOVELIST.

DR. ARABELLA KENEALY is the writer of a work of fiction, entitled *Dr. Janet of Harley Street*, which has reached its fourth edition. She is said to have gone through a complete training in medicine with the express purpose of employing the knowledge thus gained in the construction of novels. Early in life she had displayed a good literary talent, and conceived the original notion that she was deficient in that knowledge of human nature and human motives which medical study would supply her with. She determined, therefore, to bury herself for the requisite number of years away from the literary world and obtain a medical degree, although in the eyes of many of her friends these years of study seemed little better than a waste of time. But her self-estimate appears to have been substantiated.

THE NEW VOLUME OF THE INDEX-CATALOGUE.

THE fourteenth volume of the *Index-catalogue of the Library of the Surgeon General's Office, United States Army*, recently issued, brings the vocabulary to the word Universally. It shows evidence of having been prepared with the same thoroughness and carefulness that have been brought into play in the preparation of the preceding volumes. Fourteen pages are devoted to the seventh addition to the Alphabetical List of Abbreviations of Titles of Medical Periodicals, and the text occupies 1016 pages. It is to be presumed that one volume more will complete this great work.

ITEMS, ETC.

The Athletic Life.—In the *Lancet* for October 28th we find the following abstract of a lecture delivered by Sir Benjamin W. Richardson before the Athletic Association of Birmingham: "The lecturer limited the period of the athletic career to a shorter course than is generally accepted—namely, from the eighteenth to the thirty-sixth year; but it should be understood that he meant by this the true athletic existence, in which really active contests can be carried on. Contests of a serious kind should not be attempted until the body approaches maturity and should not be continued after the time when the body comes near to middle age. A point was raised whether every person can be transformed under any trainer or under any system of training into a veritable athlete—that is to say, into one who can properly enter into a contest. It was admitted at the end of the discourse that a physically uncultivated nation might have its strength easily doubled by the introduction of a sound system of athleticism; but it was contended that among the members of communities there were always a number who, although benefited by physical exercises, could never become athletes and who ought never to attempt to reach the position. A distinction was thus raised as between common physical exercise and the trained exercise intended for the purposes of competition. A speaker, Mr. Mathews, in moving a vote of thanks to the lecturer, explained that he, a Swiss mountain climber, kept up his climbing feats although he was sixty years of age—viz., twenty-four years of age beyond the period that

had been specified. But that is not athleticism, was the reply; it is common exercise that requires no trainer, and, although it is risky, it does not come into the sphere of the athletic life. Here is a question that opens up a wide field of controversy among those who have made athletic pursuits a part of their practical studies. Is there a line of demarcation between athletic exercise and systematic common exercise? The answer, we presume, will be that there is such a line of demarcation, and that the term 'athleticism' is only applicable to pursuits where competition comes into play and where perhaps a course of training is required for success. This evidently was Sir Benjamin Richardson's view, and he mentioned, as the qualities to be developed by such training, precision, decision, presence of mind, and endurance. These qualities are of a mixed sort, being partly physical and partly mental, but their interrelation is very intimate, and it is easy to see that their joint employment must result in the perfection of athletic prowess, in whatever department of athleticism they are displayed. At the same time the four qualities had not, in the lecturer's eye, an equal value; mental endurance, the other qualifications being in fair condition, stood first. A comparatively feeble development of body could be made effective by mental endurance, and some most important physical difficulties could be overcome by strength and endurance of will aiding and sustaining endurance of a physical kind. Several striking examples were supplied in which mental endurance carried the day, and it was shown that pure physical accomplishment, great as it might be, was of little avail when not backed up by the strength of the natural and commanding mind. In other words, mere strong savagery could not make either a nation or a man physically great; there must be that inborn faculty or quality which, though not measurable, nor to be weighed, nor in substance visible, becomes in action the essential virtue, the power that wins—the same virtue that sustains the orator, the writer, and the discoverer, and that belongs in the highest degree to the highest civilization."

The Use of the Title of Doctor is under discussion in the *British Medical Journal*. In its issue for October 21st the *Journal* prints the following:

J. L. C. writes: I think the remarks made by "M. D. and M. B." on this subject are deserving of a retort. In the first place, I should like to ask him who it is that gives the physician and surgeon the title of "doctor?" The patients and the public are the criminals. When a person is ill he does not say, "Go and fetch the M. R. C. S. E.," but says, "Fetch a doctor"; and when the medical man arrives he is called "Doctor." If your correspondent will take the trouble to look at *Nuttall's Dictionary* he will find that such language is quite correct. Nuttall says "doctor" means "a learned man," "a physician," "a fish with sharp-edged spines near the tail," etc. It has been the custom from time immemorial to call physicians "doctors," and I hope it will continue, in spite of the hasty remarks of "M. D. and M. B."; and I also hope the Medical Defense Union (of which I am a member) will continue to apply their funds to a better object than that which is proposed by "M. D. and M. B.," unless at the same time Dr. Leslie Phillips prosecutes M. D.'s and M. B.'s who call themselves physicians without having a diploma from a college of physicians. If a medical man puts M. D. after his name when he is not entitled to it, he ought to be punished; but when a medical man puts "Dr." before his name on his card or doorplate, it is only to show that he practices medicine. A great many men holding an M. D. degree will not allow themselves to be called "doctor," simply because they do not practice medicine, but surgery. Perhaps "M. D. and M. B." would prosecute them for calling themselves

"Mr.'s." "M. D. and M. B.'s" remarks about raising the status of the profession and improving general education are quite uncalled for. I have known M. D.'s of British universities no better educated than board schoolboys, and altogether deficient in gentlemanly manners.

A registered M. D. (registered as such in the first *Register* issued) writes: In reply to "M. D. and M. B.," in the *Journal* of October 7th as to the title of "Dr." which is now being used by a large number of practitioners, not only on their doorplates but also on their cards, without being legally entitled to adopt the title, the time certainly has arrived that such illegality should be discountenanced, particularly after the opinion expressed a short time since at the High Court that no one unless a registered M. D. can style himself "Dr."; also with twopenny dispensaries and usurpation of a title to which the majority of medicals are not entitled, thus assuming a false position in the estimation of the public. Why do not the different colleges—who do not grant degrees, merely qualifying diplomas—exercise their authority in the matter and not allow their members and licentiates to palm themselves upon the general public as doctors? Even the licentiates of the College of Physicians, London, are styling themselves "doctors," contrary to the by-laws issued by that college. The College of Physicians, Edinburgh, seems to have been the first aggressor in permitting their licentiates to use the title—especially in the year of grace when their diploma was to be had by the payment of £10. They can call themselves "physicians" but not "doctors"—thereby meaning, which can not be accepted in any other light, that they are M. D.'s. In any profession a man calling himself "Dr." must be a doctor of something, whether of divinity, laws, medicine, or music. It is high time the question should be finally settled, and I trust before long the Medical Defense Union will be prepared, under its present able president, to take legal proceedings in the matter. It does seem now more respectable to call one's self plain "Mr.," especially in these days, when the status of the profession seems to be somewhat ignored by many medicals who are carrying on their work in a degrading fashion, such as cheap physic and advice, as also taking unto themselves titles which are false and deceptive to the public. As now constituted there are: Doctors—that is, doctors of medicine, M. D.'s; physicians of a college of physicians and surgeons; ditto surgeons. At present L. S. A.'s are without title, some of whom are now styling themselves "doctors."

Common Sense writes: The subject of the title "Dr." appears to have had great interest for a certain number of gentlemen for some years past, but I have failed to observe the names of any important M. D.'s among the number of those condemning its use among general practitioners, and I take it that the obscurity of those who thus object to its use is the very essence of their militating against its being used by any but M. D.'s. An M. D. holding important posts and in good practice would scorn to interfere with his more humble neighbor, because he found it simpler, more convenient, and less conspicuous to have a small doorplate with "Dr. So-and-so" on it, and how can this touch the interests of those M. D.'s who complain of it? They can put "John So-and-so, M. D.," and what more can they want, and what can possibly show more their great superiority over their more humble brother?

Again, it is but an act of selfishness on their part, for if they use their magic letters they can not use the title "Dr." with any decent taste, and if they use this title they must drop the letters. It seems to me the whole matter is contained in a nutshell, and is a question of success or non-success. If a man has the qualities and manner for a successful doctor, a successful doctor he will be, even though he may not be the doctor

with the big D.; and, on the other side, however many letters of the M. D. class a man may hold, he will fill but an indifferent position if he has not these special qualities, and it seems, in my humble opinion, that it is this latter class who have mistaken their vocation, who clamor so loud at what they are pleased to consider their special domain being trespassed upon. An improper assumption of titles is greatly to be deprecated, but it is no more an assumption, in my opinion, to use "Dr." on a doorplate by every qualified doctor than it is for every minister of religion to call himself "Rev."

F. W. C. writes: There is little doubt that, were the general public educated in this matter as regards the intrinsic worth of the variety of medical titles and the various standards required by the different universities and colleges, there would be no hardship for many practitioners to be called "Mr." But as the public is so uneducated on this subject, and so imbued with the idea that a physician or surgeon must necessarily be a doctor, it is a great hardship to well-qualified men, who have passed, it may be, a higher standard of examination than men holding an M. D. degree, to be considered their inferiors from a professional point of view. The General Medical Council require that all examining bodies (corporations as well as universities) shall keep up a certain standard of proficiency. But they in no way insist that the universities shall retain a higher one in their examinations. And I would further point out that the reports of this body are not always universally favorable to the would-be superior examining boards, the universities.

I would respectfully suggest that all M. D.'s should always notify after their names where their doctorate is obtained, as it is only fair, I think, to licentiates to do so until the time comes when the Government of this country shall institute a State examination.

M. D. and Physician writes: Would it be considered peculiar or incorrect for the L. or M. R. C. P. to place on his doorplate "Physician" after the name, omitting "Surgeon" if not practicing as such? If correct, that would settle the dispute about the title of "Dr." (one used by some M. R. C. P.'s as a right, others by courtesy), provided that the M. D.'s do not usurp the right to the title of physician, a far more respectable and highly-thought-of address than the other, which is too often mixed up with the retail of lollipops, tooth brushes, quack medicines, and consultations, medicines included, at the charge of 6d., or clubs at 2s. 6d. a head. Physicians are not permitted to do so. Such conduct is more damaging than the misuse of titles.

Dr. A. Sheen (Cardiff) writes: If I had the power I would solve this question in the following manner: Every registered medical practitioner should have the right to style himself a "doctor," just as every lawyer is styled a "solicitor." This would not imply that he was an M. D. He should put on his card or his plate—

Mr. ———,
Doctor.

The public calls us "doctors," but in print we are spoken of as "medical men," "medical gentlemen," or "medical practitioners"—absurd titles; as is also the one which we frequently see on a doorplate—namely, "Physician and Surgeon." Can not some leaders in the profession, or members of the General Medical Council, take this matter up in the way I have suggested, and once for all do away with an absurd anomaly?

B. A., M. B., B. Ch. writes: The writers of the letters which have appeared on the subject of the title of "Dr." seem to ignore the fact that even among M. D.'s differences exist as regards status. In some cases, though a man may write M. D., he has never passed any arts examination except a preliminary one; others have taken the B. A. degree and perhaps the M. A.

by choice; while others come from universities which have refused to become for any one merely medical colleges, insisting that no degrees in special subjects shall be given till the B. A. examination shall have been passed. Surely if the M. D.'s — B. A. are to be allowed to look down on licentiates, the M. D.'s + B. A. may look in slightly similar direction on the M. D.'s — B. A.

H. R. writes: I have often noticed that M. D.'s describe themselves on their doorplates as "Dr. —, Physician and Surgeon." Strictly speaking, they are doctors of medicine and surgery, and have no more right to describe themselves as physicians than a licentiate has to describe himself as M. D. They will answer, "An M. D. is a physician." I say he is not, unless a physician or licentiate in medicine is a doctor. Your correspondent wants to gain the advantage of his M. D., and at the same time claim the diploma of physician without earning it. If a degree in medicine were only granted to B. A.'s, as in Dublin, then the graduates might be justified in feeling pride in their knowledge of general literature, but the B. A. is not generally compulsory. "M. D., M. B." suggests that the Medical Defense Union should take the matter up, and proceed against physicians who call themselves "Dr." May I conclude by asking how long that society would last if it followed this suggestion?

"Indian Fire."—Under this heading the *Medical News* for November 4th publishes the following letter from Dr. J. O. Ballard, of Natchez, Mississippi, the chief health officer of Adams County:

"My attention was first called to this disease late last summer, and being unable to properly classify it, I made a study of it. The older physicians call it 'Indian fire,' but seem unable to explain its pathology. Some confound it with variella, and there are cases that resemble this. In the proper place I shall show the points of distinction between the two. 'Indian fire' presents several distinct characteristics, but I have been unable to find a description of it in any text-book or cyclopædia.

"It is best defined as a specific infectious disease of the skin, not accompanied by constitutional disturbance. It begins as a bunch of tiny vesicles thickly studded over a reddened area. There may be one, two, or more bunches, and the vesicles vary in size from that of a mustard seed to that of a bleb from one fourth to five eighths of an inch in diameter. In a few cases I have seen, the vesicles were widespread; but generally they are found only in a circumscribed area. The large vesicles are, probably, aggregations of small ones. There is no pain, no fever, but after the eruption appears the affected area has a peculiar burning sensation; if this be scratched, or the vesicles be broken, the itching is intense.

"The diagnosis is not easy. The affection is often confounded with herpes. But the absence of pain and constitutional disturbance, the length of time the disease lasts, and its undoubted power of infection, clearly distinguish it from herpes.

"It may also be mistaken for varicella, but there are three points of distinction: 1. The entire absence of fever. 2. The course and termination. 3. The location and distribution of the lesions.

"The treatment is important. If seen early, the case is well in five or six days; but if neglected, as is often the case, it hangs on for weeks. I have one case that was not brought to my notice until more than six weeks had elapsed.

"If seen early, and a soothing ointment—ung. zinci oxidi, or an ointment of boric acid, powdered camphor, and lanolin—is applied, with a mild laxative daily, the eruption quickly dries up and forms a scale, which drops off in the bath, leaving a reddened but afterward normal skin, as in herpes. But if

neglected, the blisters and vesicles are broken and the intense itching keeps the parts red, and the irritation increases the flow of serum; the parts are then found constantly bathed in a sticky, gummy fluid. In the cases that have come under my observation the favorite location of the lesions was the face and neck, usually in both places at the same time."

The late Dr. Alfred Ludlow Carroll.—The members of the council of the New York State Medical Association deeply mourn the loss of their beloved, erudite, scholarly, and gentle colleague, Alfred Ludlow Carroll, M.D., who has labored so well and so assiduously for the association, for the profession, and for the people as a wise counselor, as the editor of the association's *Transactions*, as a prolific contributor of scientific material, as a promoter of the honor, dignity, and advancement of medical science, and as one of the foremost sanitarians in the land.

The council has therefore resolved that their high appreciation of the noble qualities and of the scientific accomplishments of their late gifted and lamented colleague be recorded in this volume of *Transactions* and in the medical journals, and that a copy of the foregoing be transmitted to the family of the deceased.

E. D. FERGUSON, M. D., *Secretary*.

Done by the Council, November 4, 1893.

The Death of Dr. Samuel Gilman Priest occurred on October 27th, at Taunton, Mass., where he was visiting at the time of his last illness. Dr. Priest was born in Marlborough, about sixty-six years ago. He was an alumnus of Bellevue Hospital Medical College, of the class of 1877. His home in recent years had been in West Ninety-fourth Street.

The Death of Dr. Charles Wesley Stanley took place in New York on the 26th ultimo. He was born in Conway, N. H. He received his early education at the Oneida Institute, and was graduated in 1866 from the Medical Department of the University of the City of New York. In 1870 he moved to Chicago, where for over twenty years he was actively engaged in the practice of his profession. Dr. Stanley was quiet and retiring in disposition and a devoted student. As a physician he was capable and sympathetic, and by his kindly nature he endeared himself to all with whom he came in contact. He was married in 1869 to Miss Harriet Armstrong, who survives him.

The New York State Association of Railway Surgeons.—

The third annual meeting will be held in the New York Academy of Medicine's building on Wednesday, the 15th inst., under the presidency of Dr. George Chaffee, of Brooklyn, in addition to whose address the programme announces the following: A Dissertation on the Transportation of Persons Ill with Contagious or Infectious Disease, by Dr. G. P. Conn, of Concord, N. H.; The Duties of Chief and Local Surgeons, by Dr. G. J. Northrop, of Marquette, Mich.; The Railway Hospital—its Necessity and Benefits, by Dr. Frank H. Caldwell, of Sanford, Florida; Unjust Verdicts in Civil Damage Suits, by Dr. J. S. Wight, of Brooklyn; The Influence of the Attending Physician in Litigation Cases, by Dr. M. D. Field, of New York; The Evolution of the Railway Surgeon, by Dr. R. S. Harnden, of Waverly, N. Y.; A Peculiar Result of an Injury, by Dr. C. M. Daniels, of Buffalo; Traumatic Ankylosis, by Dr. S. H. Manley, of New York; and Ophthalmology in Railway Surgery, by Dr. J. E. Weeks, of New York.

The Society of Medical Jurisprudence.—At the next meeting, on Monday evening, the 13th inst., the Hon. David McAdam will read a paper on Malpractice. The annual din-

ner will take place at the Hoffman House on Saturday, December 16th.

The Shelby County, Indiana, Medical Society.—At the next meeting, on Monday, the 13th inst., papers will be read as follows: Thorough Knowledge of a Few Remedies, by Dr. J. W. Snider; Palatable Prescribing, by Dr. Samuel Kennedy.

Changes of Address.—Dr. S. Pollitzer, to No. 32 East Sixtieth Street; Dr. F. A. Manning, to No. 203 West One hundred-and-third Street.

The City (Charity) Hospital.—Dr. Robert W. Taylor, whose resignation from the attending staff we announced last week, has been appointed a consulting surgeon to the hospital.

The Death of Sir Andrew Clark, of London, is announced as having taken place on Monday, the 6th inst.

Professor Helmholtz.—The *Union médicale* states that Professor Helmholtz was severely injured on board the steamer *Saale* on his recent return from America.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 22 to November 4, 1893:*

SKINNER, JOHN O., Major and Surgeon, having been found incapacitated for active service on account of disability incident to the service, is, by direction of the President, retired from active service this date, October 26, 1893, under the provisions of Section 1251, Revised Statutes.

IVES, FRANCIS J., Captain and Assistant Surgeon, is relieved from temporary duty with the Medical Section of the War Department Exhibit, World's Columbian Exposition, Chicago, Ill., and will return to his proper station, Fort Sheridan, Illinois.

KULP, JOHN S., First Lieutenant and Assistant Surgeon, now on duty at Columbus Barracks, Ohio, will proceed to Jackson Park, Chicago, Ill., and report in person to the commanding officer, Camp Lamont, for temporary duty with the battalion of troops stationed there.

MUNN, CURTIS E., Major and Surgeon, is hereby granted leave of absence for one month, with permission to apply for an extension of two months.

WYETH, MARLBOROUGH C., Captain and Assistant Surgeon, is relieved from duty at Fort Supply, Indian Territory, and ordered to Army and Navy General Hospital, Hot Springs, Arkansas, for duty.

BENHAM, ROBERT B., Captain and Assistant Surgeon, having relinquished unexpired portion of sick leave, is ordered to Madison Barracks, New York, for duty.

HALLOCK, HARRY M., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort McPherson, Georgia, and ordered to Fort Bayard, New Mexico, for duty, relieving First Lieutenant and Assistant Surgeon Philip G. Wales. First Lieutenant Wales, on being relieved by Lieutenant Hallock, is ordered to Fort McPherson, Georgia, for duty.

BIRMINGHAM, H. P., Captain and Assistant Surgeon. The leave of absence granted is extended twenty-three days.

LYNCH, CHARLES, First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Omaha, Nebraska, and ordered to Fort Robinson, Nebraska, for duty at that station, relieving EVERTS, EDWARD, Captain and Assistant Surgeon. Captain Everts, on being relieved by Lieutenant Lynch, is ordered to Whipple Barracks, Arizona, for duty, relieving POPE, BENJAMIN F., Major and Surgeon. Major Pope, on being relieved by Captain Everts, is ordered to Angel Island, California, for duty, relieving HALL, WILLIAM R., Captain and Assistant Surgeon. Captain Hall, on being relieved by Ma-

for Pope, will report for duty as Attending Surgeon, Headquarters Department of California and Examiner of Recruits at San Francisco, Cal.

TILTON, HENRY R., Lieutenant Colonel and Deputy Surgeon General, is relieved from duty at Fort Wayne, Michigan, and ordered to Fort Omaha, Nebraska, for duty at that post.

MAUS, LOUIS M., Major and Surgeon, is relieved from duty at Whipple Barracks, Arizona, and ordered to Fort Sam Houston, Texas, for duty, relieving DE WITT, CALVIN, Major and Surgeon. Major De Witt, on being relieved by Major Maus, is ordered to Fort Leavenworth, Kansas, relieving BROOKE, JOHN, Major and Surgeon. Major Brooke, on being relieved by Major De Witt, is ordered to Philadelphia, Pa., to await orders.

MIDDLETON, JOHNSON V. D., Lieutenant Colonel and Deputy Surgeon General. The leave of absence granted is extended fifteen days.

Marine-Hospital Service.—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Five Weeks ending October 21, 1893:*

FRESSENFEN, C. D., Surgeon. Granted leave of absence for thirty days. October 4, 1893.

BALHAUCHE, P. H., Surgeon. Detailed as delegate to meeting of the American Public Health Association. October 5, 1893.

VANSANT, JOHN, Surgeon. Granted leave of absence for thirty days. September 23, 1893.

HUTTON, H. H. Surgeon. Detailed as chairman of board to inspect Gulf Quarantine Station. October 17, 1893.

HAMILTON, J. B., Surgeon. Granted leave of absence for three days. October 2, 1893.

GASSAWAY, J. M., Surgeon. Detailed as member of a board to inspect Gulf Quarantine Station. October 17, 1893.

MEAD, F. W., Surgeon. To rejoin station (Washington, D. C.). September 19, 1893.

CARTER, H. R., Surgeon. To proceed to Way Cross, Ga., for temporary duty. October 4, 1893.

KALLOCH, P. C., Passed Assistant Surgeon. Granted leave of absence for twenty days. October 9, 1893.

BROOKS, S. D., Passed Assistant Surgeon. To proceed to Chicago, Ill., for temporary duty. September 19, 1893.

GOODWIN, H. T., Passed Assistant Surgeon. Granted leave of absence for thirty days. September 27, 1893.

COBB, J. O., Passed Assistant Surgeon. Granted leave of absence for thirty days. October 11, 1893.

PERRY, J. C., Passed Assistant Surgeon. Granted leave of absence for seven days. October 5, 1893.

GARDNER, C. H., Assistant Surgeon. To proceed to Port Townsend, Wash., for temporary duty. October 7, 1893.

NYDEGGER, J. A., Assistant Surgeon. To proceed to Way Cross, Ga., for temporary duty. October 8, 1893.

NORMAN, SEATON, Assistant Surgeon. Granted leave of absence for four days. October 4, 1893.

SPRAGUE, E. K., Assistant Surgeon. Granted leave of absence for three days. October 7, 1893.

Society Meetings for the Coming Week:

MONDAY, November 13th: New York Academy of Medicine (Section in General Surgery); Lenox Medical and Surgical Society (private); New York Ophthalmological Society

(private); New York Medico-historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Boston Society for Medical Improvement; Gynecological Society of Boston; Burlington, Vt., Medical and Surgical Club (annual); Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

TUESDAY, November 14th: Southern Surgical and Gynecological Association (first day—New Orleans); New York Academy of Medicine (Section in Genito-urinary Surgery); New York Medical Union (private); Kings County, N. Y., Medical Association; Medical Society of the County of Rensselaer, N. Y.; Clinical Society of the Elizabeth, N. J., General Hospital and Dispensary; Newark, N. J., and Trenton (private), N. J., Medical Associations; Camden, N. J., County Medical Society (semi-annual—Camden); Norfolk, Mass., District Medical Society (Hyde Park); Baltimore Gynecological and Obstetrical Society; Northwestern Medical Society of Philadelphia; Practitioners' Club, Richmond, Ky.; Richmond, Va., Academy of Medicine and Surgery.

WEDNESDAY, November 15th: Southern Surgical and Gynecological Association (second day); Harlem Medical Association of the City of New York; Northwestern Medical and Surgical Society of New York (private); Medico-legal Society, New York; New Jersey Academy of Medicine (Newark).

THURSDAY, November 16th: Southern Surgical and Gynecological Association (third day); New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, November 17th: Baltimore Clinical Society; Chicago Gynecological Society.

SATURDAY, November 18th: Clinical Society of the New York Post-graduate Medical School and Hospital.

Answers to Correspondents:

No. 447.—1. The physician can bring suit for the full amount of his bill. 2. That depends on the jury's finding. 3. Obtain the services of a lawyer. 4. They are prone to exercise such power, and there is no remedy save in a suit. 5. Under the common law, no, but there may be a statute covering the point in your State; if there is, it is probably unconstitutional.

Letters to the Editor.

THE QUESTION OF THE INFECTIOUSNESS OF "MEMBRANOUS CROUP."

HEALTH DEPARTMENT, 301 MOTT STREET,
NEW YORK, November 3, 1893.

To the Editor of the New York Medical Journal:

SIR: The accompanying report by the chief inspector of the Division of Pathology, Bacteriology, and Disinfection of this department is of very great interest to the medical profession and of great importance to the community. The board of health requests the co-operation of the physicians of this city in order to definitely establish or refute the contagiousness of so-called membranous croup. The fact that in a large majority of the cases of membranous croup (not apparently involving the pharynx) examined bacteriologically by the officers of this department swabs infected with the pharyngeal secretions were shown to contain the Loeffler bacillus tends to the conclusion that membranous croup is laryngeal diphtheria, and that, as is shown in the report, it is liable to cause cases of like character or of diphtheria of the ordinary type. Before declaring the

disease contagious and classing it among the transmissible diseases which must, under the law, be reported to the board of health, the board desires to have the results of the bacteriological investigation of a large number of cases of membranous croup tabulated, in order to base its action on irrefutable premises. The only way that this can be done is through the voluntary report to this department by physicians of cases of membranous croup that may occur in their practice.

Therefore the board respectfully requests physicians to report cases of membranous croup under that name, in the same manner that they report cases of contagious disease. The data already obtained are sufficiently convincing to cause this request to the profession to treat membranous croup as a contagious disease: that is, to advise isolation and disinfection the same as in a case of diphtheria.

CYRUS EDSON,

Commissioner, and Chairman of the Sanitary Committee of the Board of Health of New York City.

HEALTH DEPARTMENT, 301 MOTT STREET,
NEW YORK, November 1, 1893.

The Hon. Charles G. Wilson, President:

SIR: In compliance with your request I have the honor to submit the following report of the results of the bacteriological examinations made in cases of so-called membranous croup. These are cases from which cultures have been referred to this department for examination because of the suspicion that they were of a diphtheritic nature.

During the last four months bacteriological examinations have been made in thirty-six cases of this kind. In all of these the membrane was either confined entirely to the larynx, or at most only slight deposits existed in the throat, while there was very extensive exudation in the larynx. In thirty of the cases the Loeffler bacillus of diphtheria was abundantly present. These cases therefore were really cases of laryngeal diphtheria. In six cases no Loeffler bacilli were found; these were therefore cases of catarrhal pseudo-diphtheritic inflammation of the larynx, and are to be considered analogous to similar pseudo-membranous inflammations (non-diphtheritic) in the pharynx.

In five of the laryngeal cases in which the Loeffler bacillus was found, cases of pharyngeal diphtheria both preceded and followed within a week in the immediate vicinity. In three other instances the cases of croup were preceded by cases of true diphtheria, and in seven instances were followed by cases of true diphtheria.

In the remaining fifteen cases of membranous croup pharyngeal diphtheria neither preceded nor followed in the immediate vicinity. None of the six cases of croup in which no Loeffler bacilli were found were followed or preceded by cases of diphtheria.

During the last four months, therefore, nearly eighty-four per cent. of the cases of so-called membranous croup referred to this department for bacteriological examination have proved to be diphtheria.

Respectfully,

HERMANN M. BRIGGS, *Chief Inspector.*

AMPUTATION AT THE HIP JOINT.

To the Editor of the New York Medical Journal:

SIR: While a minor paragraph of your issue of November 4th, upon the subject of the amputation at the hip joint, is mainly correct in the lines quoted from Professor Murdoch's excellent paper in the *Annals of Surgery* (January, 1893), the construction of the paragraph is, I think, calculated to mislead. Professor Murdoch says: "It was reserved for our countryman, Dr. John A. Wyeth, to devise what he has well named the bloodless method. I believe this method to be the best and

the one destined to supersede all other methods for the temporary arrest of hæmorrhage."

The method of operating known as that of Fourneau-Jordan, referred to in your paragraph, has *nothing to do with the prevention of hæmorrhage*, but relates to the method of making the flaps.

This same method of cutting the skin and soft parts is also frequently referred to as Diefenbach's. The truth is that Diefenbach did not receive his degree in medicine until sixteen years after Dr. Walter Brashear, of Kentucky, had done this operation successfully. "A circular incision was made, the muscles divided well below the hip joint, and the vessels secured as the operation progressed. Then a longitudinal incision along the outer side of the limb exposed the remainder of the bone, which, being freed from its muscular attachments, was disarticulated at the socket." This was in August, 1806 (*American Practitioner and News*, Professor David W. Yandell, 1890). The name of Brashear should forever be associated with this brilliant operation.

JOHN A. WYETH, M. D.

ATHETOSIS DUE TO TRAUMATISM.

LINCOLN, NEB., October 20, 1893.

To the Editor of the New York Medical Journal:

SIR: In your issue of October 7th there is an article by Dr. T. J. McGillicuddy on Athetosis, which recalls to my mind a patient that came under my observation about five years ago. As this sketch is written entirely from memory, I have not attempted to give any of the minute details. I saw the patient but once, and then for only a short time. As the parents were in no condition to place her in a suitable position for treatment, I made no record of the case. The patient, a girl about fourteen or fifteen years of age, well nourished and fully developed, was greatly troubled with athetoid spasms on the right side, most severe in the right forearm and hand. Both sides of the body appeared equally developed. When the spasms came on the forearm and hand were rotated inward so as to nearly or quite inscribe an arc of 180°, so that the palmar surface of the hand turned outward. At times the spasms would completely relax, but when they were most severe, if the arm and hand were thoroughly rubbed for a few seconds, the spasm would be relieved and the limb would remain for some little time perfectly natural. The lower right limb and foot were also turned in, although not to the same extent as the hand and arm. Mentally the girl appeared perfectly normal and answered all questions put to her readily and as intelligently as most girls would have done at her age. Now as to the cause given by the parents. When she was about five years of age a fork tine was accidentally run into the inner canthus of the left eye for nearly two inches. In a few hours after, the girl was found to be completely paralyzed on the right side. This condition continued for several weeks, when the child, without any treatment, gradually regained the use of her arm and leg, only to have substituted for the paralysis the athetoid condition above described. To me it seems perfectly clear that the athetosis in her case was due to the traumatism.

H. S. ALEY, M. D.

INFANTILE CONVULSIONS.

CHICAGO, October 30, 1893.

To the Editor of the New York Medical Journal:

SIR: Apropos of the article on Infantile Convulsions by M. Jules Simon, summarized in the *Journal* for October 28th, I would offer the *hypodermic injection* of five grains of chloral hydrate for an infant aged two years as a most gratifying mode of treatment in these trying cases.

J. P. PRESTLEY, M. D.

Book Notices.

Beiträge zur Augenheilkunde; herausgegeben von Prof. Dr. R. DEUTSCHMANN in Hamburg. Hamburg: Leopold Voss, 1891-1893. Hefte iii to x.

THESE are brochures of varying size which have appeared at irregular intervals during the last two years. They contain a very interesting series of articles by various German authors. Professor Fuchs, of Vienna, reports an interesting case of simultaneous inflammation of the lacrymal and parotid glands, occurring in a man aged sixty-one years. In both glands the tissue of the nodular tumors closely resembled the lymphoid tissue of trachoma follicles.

In an article* by Professor Haab, of Zurich, upon the treatment of infantile glaucoma or hydropthalmia, he highly recommends sclerotomy as the most certain method of treatment and the most lasting in its effects.

Another interesting paper is by Pedraglia, of Hamburg, on the disturbances in the domain of the ocular nerves produced by poisoning with diseased ham. The first symptom to appear is paralysis of accommodation, and this is rapidly followed by paresis of the muscles of the throat. Then follow mydriasis, diplopia, and ptosis. Most of the cases, if promptly treated, end in recovery. A brief article by Lindemann on the pseudotumors of the interior of the eye is based upon two cases of cataract extraction, in which, shortly after the operation, symptoms of an intra-ocular growth appeared, the most marked being a glistening, grayish-yellow reflex from the fundus, simulating tumor. In both cases this proved to be due to portions of swollen cortex of the lens left behind in the vitreous humor.

Haab, of Zurich, publishes an exceedingly interesting article on hæmorrhages between the retina and the vitreous, based upon a series of six cases and illustrated by six beautiful chromolithographic plates. Another timely article is by Deutschmann himself on acute retrobulbar neuritis of rheumatic origin, based on a series of seven cases. In all the cases the visual defect appeared suddenly, and was accompanied by pain on movements of the eyeball. The defect in the visual field varied among central, peripheral, and sector-like peripheral defects. In all cases there was color-blindness more or less marked. The ophthalmoscope showed in all cases a decided change in color and appearance of the disc. In one case there was a relapse accompanied by paralysis of the abducens. The treatment which proved the most efficacious was the administration of sodium salicylate and potassium iodide.
